PATHOPHYSIOLOGY

Asthma is a chronic airway inflammatory disease stemming from the effects of numerous inflammatory cells and mediators to manifest in clinical characteristics and pathophysiological changes leading to expiratory airflow limitation.[2] Airway narrowing is the ultimate endpoint of the inflammatory processes and is a function of airway smooth muscle contraction, with potential remodeling due to structural changes, and airway plugging by mucus hypersecretion which leads to the common symptoms of asthma, wheeze, shortness of breath, chest tightness, and/or cough. Symptoms may be intermittent (weeks or months between symptoms) or may occur frequently and may resolve spontaneously or following treatment. Over time, asthma can progress to persistent airflow limitations. In addition, bronchial hyperresponsiveness (BHR) is a characteristic functional abnormality of asthma and is the heightened response to a stimulus (eg, cat dander) not observed in healthy individuals that enhances the susceptibility to airway narrowing.[2]

To understand the pathogenetic mechanisms that underlie the many asthma phenotypes, it is critical to identify factors that initiate, intensify, and modulate the inflammatory response of the airways and to determine how these processes produce the characteristic airway abnormalities. Current and evolving treatments target these inflammatory processes (Fig. 44-2).

Inflammatory Processes

Airway inflammation is multifaceted and the primary focus of asthma management and prevention. It has been demonstrated in all forms of asthma, and an association between the extent of inflammation and the clinical severity of asthma has been demonstrated in selected studies. Both central and peripheral airways are inflamed.

The use of inhaled allergen challenge models has contributed significantly to understanding the inflammatory cascade in the airways. Allergen inhalation in allergic patients causes an early-phase reaction (within minutes) that, in some cases, may be followed by a late-phase reaction (hours later). The early phase is initiated by the activation of cells bearing allergen-specific immunoglobulin E (IgE). It is characterized by the rapid activation of airway mast cells and macrophages leading to the rapid release of pro-inflammatory mediators such as histamine, eicosanoids, and reactive oxygen (O_2) species that induce contraction of airway smooth muscle, mucus secretion, and edema. The bronchial microcirculation has an essential role in this inflammatory process. Inflammatory mediators induce microvascular leakage with the exudation of plasma in the airways. Acute plasma protein leakage induces a thickened, engorged, and edematous airway wall and a consequent narrowing of the airway lumen. Plasma exudation may compromise epithelial integrity, and the presence of plasma in the lumen may reduce mucus clearance. Plasma proteins also may promote the formation of exudative plugs mixed with mucus and inflammatory and epithelial cells. Together these effects contribute to airflow obstruction (see Fig. 44-2).

The late-phase inflammatory reaction occurs 6 to 9 hours after allergen provocation and involves the recruitment and activation of eosinophils, CD4$^+$ thymically derived lymphocytes (T-cells), basophils, neutrophils, and macrophages.[16] There is selective retention of airway T-cells, the expression of adhesion molecules, and the release of selected pro-inflammatory mediators and cytokines involved in the recruitment and activation of inflammatory cells.[16] The activation of T-cells after allergen challenge leads to the release of Th$_2$-related cytokines that may modulate the late-phase response.[16] The release of preformed cytokines by mast cells is the likely initial trigger for the early recruitment of inflammatory cells that then recruit and induce the more persistent involvement by T-cells.[9,16] The enhancement of nonspecific BHR usually can be demonstrated after the late-phase reaction but not after the early-phase reaction following allergen or occupational challenge.

In asthma, all cells of the airways are involved and become activated (Fig. 44-2). Included are eosinophils, neutrophils, T-cells, mast cells, alveolar macrophages, and dendritic cells, epithelial cells, fibroblasts, and bronchial smooth muscle cells. These cells also regulate airway inflammation and initiate the process of remodeling by the release of cytokines and growth factors.[17]

Inflammatory Cells

Epithelial Cells

Bronchial epithelial cells participate in mucociliary clearance and removal of noxious agents. Stimuli such as allergens and air pollution stimulate epithelial cells to release various cytokines such as eicosanoids, peptidases, matrix proteins, periostin, cytokines, chemokines, and nitric oxide (NO).[16] Periostin is an extracellular matrix protein secreted by epithelial cells that induces the inflammatory cytokines, interleukin 4 (IL-4), and interleukin 13 (IL-13).[18] It has become important more recently as a biomarker of persistent eosinophilic airway inflammation and may have an integral role in airway remodeling, subepithelial fibrosis, and mucus regulation.[18,19] Epithelial cells can be activated by IgE-dependent mechanisms, viruses, pollutants, or histamine. In asthma, especially fatal asthma, extensive epithelial shedding occurs. The functional consequences of epithelial shedding may include heightened BHR, the release of the chemokine eotaxin that attracts eosinophils, altered permeability of the airway mucosa, depletion of epithelial-derived relaxant factors, and loss of enzymes responsible for degrading pro-inflammatory neuropeptides. The integrity of airway epithelium may influence the sensitivity of the airways to various provocative stimuli. Epithelial cells may also be important in the regulation of airway remodeling and fibrosis.[9,16]

Eosinophils

Eosinophils play an effector role in asthma by releasing pro-inflammatory mediators, cytotoxic mediators, and cytokines.[9] Circulating eosinophils migrate to the airways by cell rolling, through interactions with selectins, and eventually adhere to the endothelium through the binding of integrins to adhesion proteins (vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). As eosinophils enter the matrix of the membrane, their survival is prolonged by IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, eosinophils release inflammatory mediators such as leukotrienes (LTs) and granule proteins to injure airway tissue.[9]

Lymphocytes

Mucosal biopsy specimens from patients with asthma contain lymphocytes, many of which express surface markers of inflammation. There are two types of T-helper CD4$^+$ cells. Th$_1$ cells produce IL-2 and interferon-γ (IFN-γ), both essential for cellular defense mechanisms. Th$_2$ cells produce cytokines (IL-4, IL-5, and IL-13) that mediate allergic inflammation. It is known that Th$_1$ cytokines inhibit the production of Th$_2$ cytokines, and vice versa. It is hypothesized that allergic asthmatic inflammation results from a Th$_2$-mediated mechanism (an imbalance between Th$_1$ and Th$_2$ cells).[16] However, it has also been observed that there exists a low Th$_2$ cytokine phenotype of asthma in adults that appears more resistant to usual therapies for asthma.[16]

Th$_1$ and Th$_2$ Endotypes

Th$_2$ high asthma is characterized by activation of mediators such as IL-25 and IL-33 which subsequently activate IL-4, IL-5, and IL-13, as well as non-interleukin-dependent factors such as thymic stromal lymphopoietin (TSLP).[18,19] Inflammation occurs as a result of exposure of the airway epithelium to inhaled allergens, microbes, and inhaled pollutants (thus encompassing allergic and non-allergic inflammation) and occurs in approximately half of all patients with asthma.[19] The effects of these mediators result in inflammatory cell activation and secretion of IgE as well as the airway epithelium and smooth muscle.

Th$_2$ low asthma is described as neutrophilic asthma or mixed, pauci-granulocytic asthma, and is less well understood.[18,19] Patients are typically less responsive to corticosteroids, have fewer allergic symptoms, and are diagnosed later in life.

The T-cell population in the cord blood of newborn infants is skewed toward a Th$_2$ phenotype. The extent of the imbalance between Th$_1$ and Th$_2$ cells (as indicated by diminished IFN-γ production) during the neonatal phase may predict the subsequent development of allergic disease, asthma, or both. It has been suggested that infants at high risk of asthma and allergies should be exposed to stimuli that upregulate Th$_1$-mediated responses in order to restore the balance during a critical time in the development of the immune system and the lungs.

The basic premise of the Th$_1$ and Th$_2$ imbalance is that the newborn's immune system needs timely and appropriate environmental stimuli to create a balanced immune response. Factors that enhance Th$_1$-mediated responses include endotoxin exposure, such as increased exposure to infections through contact with older siblings; and daycare attendance during the first 6 months of life.[20] Restoration of the balance between Th_1 and Th_2 cells may be impeded by frequent administration of oral antibiotics, with concomitant alterations in GI flora. Other factors favoring the Th_2 phenotype include residence in an industrialized country, urban environment exposure, diet, and sensitization to house dust mites and cockroaches.[18,19]

Mast cells

Mast cell degranulation is important in the initiation of immediate responses following exposure to allergens.[3] Mast cells reside throughout the walls of the respiratory tract, and increased numbers of these cells (threefold to fivefold) have been observed in the airways of patients with asthma and atopy.[21] Once binding of allergen to cell-bound IgE occurs, mediators such as histamine; eosinophil and neutrophil chemotactic factors; LTs C_4, D_4, and E_4; prostaglandins; platelet-activating factor (PAF); and others are released from mast cells (see Fig. 44-2). Histologic examination has revealed decreased numbers of granulated mast cells in the airways of patients who have died from acute asthma attacks, suggesting that mast cell degranulation is a contributing factor. Sensitized mast cells are also activated by osmotic stimuli to account for exercise-induced bronchospasm (EIB).[22]

Alveolar Macrophages

The primary function of alveolar macrophages in the normal airway is to serve as “scavengers,” engulfing and digesting bacteria and other foreign materials. Macrophages are found in large and small airways, ideally located for affecting the asthmatic response. A number of mediators produced and released by macrophages have been identified, including pro-inflammatory and anti-inflammatory cytokines, reactive oxygen species, and eicosanoids.[23] In addition, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which in turn amplify the inflammatory process.

Neutrophils

The role of neutrophils in the pathogenesis of asthma remains somewhat unclear because they normally reside in low numbers in the airway. Though they usually do not infiltrate tissues showing chronic allergic inflammation, they are instrumental in the inflammation arising from occupational exposures such as particulate matter, ozone, and diesel exhaust. Neutrophils can be involved in late-phase inflammatory reactions. However, high numbers of neutrophils have been observed in the airways of patients who died from sudden-onset fatal asthma and in those with severe disease.[24] This suggests that neutrophils may play a pivotal role in the disease process, at least in some patients with long-standing or corticosteroid-resistant asthma.[24] The neutrophil can also be a source for a variety of mediators, including PAF, prostaglandins, thromboxanes, and LTs, that contribute to BHR and airway inflammation.[24]

Fibroblasts and Myofibroblasts

Fibroblasts are found frequently in connective tissue. Human lung fibroblasts may behave as inflammatory cells on activation by IL-4 and IL-13. The myofibroblast may contribute to the regulation of inflammation via the release of cytokines and to tissue remodeling. In asthma, myofibroblasts are increased in numbers beneath the reticular basement membrane, and there is an association between their numbers and the thickness of the reticular basement membrane.[9]

Inflammatory Mediators

Associated with asthma for many years, histamine is capable of inducing smooth muscle constriction and bronchospasm and is thought to play a role in mucosal edema and mucus secretion.[21] Lung mast cells are an important source of histamine. The release of histamine can be stimulated by exposure of the airways to a variety of factors, including physical stimuli (airway drying with exercise) and relevant allergens.[21] Histamine is involved in acute bronchospasm following allergen exposure; however, other mediators such as LTs are also involved.

Besides histamine release, mast cell degranulation releases ILs, proteases, and other enzymes that activate the production of other mediators of inflammation. Several classes of important mediators, including arachidonic acid and its metabolites (ie, prostaglandins, LTs, and PAF), are derived from cell membrane phospholipids.[21]

Once arachidonic acid is released, it can be metabolized by the enzyme cyclooxygenase to form prostaglandins. Prostaglandin D_2 is a potent bronchoconstricting agent; however, it is unlikely to produce sustained effects and its role in asthma remains to be determined. Similarly, prostaglandin $F_2\alpha$ is a potent bronchoconstrictor in patients with asthma and can enhance the effects of histamine.[21] However, its pathophysiologic role in asthma is unclear. Another cyclooxygenase product, prostacyclin (prostaglandin I_2), is known to be produced in the lung and may contribute to inflammation and edema owing to its effects as a vasodilator.

Thromboxane A_2 is produced by alveolar macrophages, fibroblasts, epithelial cells, neutrophils, and platelets within the lung.[25] It may have several effects, including bronchoconstriction, involvement in the late asthmatic response, and involvement in the development of airway inflammation and BHR.

The 5-lipoxygenase pathway of arachidonic acid metabolism is responsible for the production of the cysteinyl LTs.[25] LTC_4, LTD_4, and LTE_4 are released during inflammatory processes in the lung. LTs D_4 and E_4 share a common receptor (LTD_4 receptor) that, when stimulated, produces bronchospasm, mucus secretion, microvascular permeability, and airway edema, whereas LTB_4 is involved with granulocyte chemotaxis.

Thought to be produced by macrophages, eosinophils, and neutrophils within the lung, PAF is involved in the mediation of bronchospasm, sustained induction of BHR, edema formation, and chemotaxis of eosinophils.[26]

Adhesion Molecules

Adhesion molecules are glycoproteins that facilitate infiltration and migration of inflammatory cells to the site of inflammation by enhancing cell-cell communication.[27] Adhesion molecules are divided into families on the basis of their chemical structure. These families are the integrins, cadherins, immunoglobulin supergene family, selectins, vascular adressins, and carbohydrate ligands.[27] Those thought to be important in inflammation include the integrins, immunoglobulin supergene family, selectins, and carbohydrate ligands, including ICAM-1 and VCAM-1.[27] Adhesion molecules are found on a variety of cells, such as neutrophils, monocytes, lymphocytes, basophils, eosinophils, granulocytes, platelets, endothelial cells, and epithelial cells, and can be expressed or activated by the many inflammatory mediators present in asthma.[27]

Nitric Oxide

NO is produced by cells within the respiratory tract. It has been thought to be a neurotransmitter of the nonadrenergic, noncholinergic (NANC) nervous system.[28] Endogenous NO is generated from the amino acid L-arginine (L-Arg) by the enzyme NO synthase.[28] Three isoforms of NO synthase exist. One isoform is induced in response to pro-inflammatory cytokines, inducible NO synthase (iNOS), in airway epithelial cells and inflammatory cells of asthmatic airways.[28] NO produces smooth muscle relaxation in the vasculature and bronchials. However, it amplifies the inflammatory process and is unlikely to be of therapeutic benefit. Investigations measuring the fraction of exhaled NO (FeNO) concentrations have suggested that it may be a useful measure of ongoing allergic lower airway inflammation in patients with asthma and for guiding asthma therapy.[28]

Airway Smooth Muscle

The airway smooth muscle extends from the trachea through the respiratory bronchioles. Total smooth muscle mass decreases rapidly past the terminal bronchioles to the alveoli, so the contribution of smooth muscle tone to airway diameter in this region is relatively small. It is possible that the increased smooth muscle mass of the asthmatic airways is important in magnifying and maintaining BHR in persistent disease. However, the hypertrophy and hyperplasia are secondary processes caused by chronic inflammation and are not the primary cause of BHR.[29]

The airway smooth muscle is innervated by parasympathetic, sympathetic, and nonadrenergic inhibitory nerves.[30] Parasympathetic innervation of the smooth muscle consists of efferent motor fibers in the vagus nerves and sensory afferent fibers in the vagus and other nerves.[30] Normal resting tone of human airway smooth muscle is regulated by vagal nerve activity. Bronchoconstriction caused by vagal stimulation occurs in the small bronchi but is absent in the small bronchioles. The nonmyelinated C fibers are the predominate nerves of the afferent system are present throughout the airways with terminals in airway smooth muscle cells, epithelial cells, and airway ganglia.[30] These nerve endings probably represent the irritant receptors of the airways. Stimulation of these irritant receptors by mechanical stimulation, chemical, and particulate irritants, and pharmacologic agents such as histamine produces reflex bronchoconstriction.[30]

The NANC nervous system has been described in the trachea and bronchi. Substance P, neurokinin A, neurokinin B, and vasoactive intestinal peptide (VIP) are the best-characterized neurotransmitters in the NANC nervous system.[30] VIP is an inhibitory neurotransmitter. Inflammatory cells in asthma can release peptidases that can degrade VIP, producing exaggerated reflex cholinergic bronchoconstriction. NANC excitatory neuropeptides such as substance P and neurokinin A are released by stimulation of C-fiber sensory nerve endings.

Remodeling of the Airways

Acute inflammation is a beneficial response to tissue injury and generally leads to repair and restoration of the normal structure and function. In contrast, asthma is a chronic inflammatory process that leads to abnormal airway healing referred to as *remodeling*.[17] Repair involves replacing parenchymal cells with connective tissue that mature into scar tissue. In asthma, remodeling leads to extracellular matrix fibrosis, an increase in smooth muscle and mucous gland mass, and angiogenesis.[17]

The precise mechanisms of remodeling the airways are under intense study. Airway remodeling is of concern because it may represent an irreversible process that can have serious sequelae including the development of chronic obstructive pulmonary disease (COPD).[17] Observations in children with asthma indicate that some loss of lung function may occur during the first 5 years of life.[17]

Mucus Production

The mucociliary system is the lung's primary defense mechanism against irritants and infectious agents. Mucus, composed of 95% water and 5% glycoproteins, is produced by bronchial epithelial glands and probleT-cells.[27] The lining of the airways consists of a continuous aqueous layer controlled by active ion transport across the epithelium in which water moves toward the lumen along the concentration gradient. Catecholamines and vagal stimulation enhance the ion transport and fluid movement. Mucus transport depends on its viscoelastic properties. Mucus that is either too watery or too viscous will not be transported optimally. The exudative inflammatory process and sloughing of epithelial cells into the airway lumen impair mucociliary transport. The bronchial glands are increased in size and the goblet cells are increased in size and number in asthma. Expectorated mucus from patients with asthma tends to have a high viscosity. The mucous plugs in the airways of patients who died in status asthmaticus are tenacious and tend to be connected by mucous strands to the goblet cells.[27] The airways of persons with asthma also may become plugged with casts consisting of epithelial and inflammatory cells. Although it is tempting to speculate that death from asthma attacks is a result of the mucous plugging resulting in irreversible obstruction, there is no direct evidence for this. Autopsies of asthmatics who died from other causes have shown similar pathology. In addition, some patients who have died of sudden severe asthma did not show the characteristic mucous plugging on necropsy.

Bronchial Hyperresponsiveness

Chronic inflammation is associated with nonspecific BHR and increases the risk of asthma exacerbations. Exacerbations are characterized by increased symptoms and worsening airway obstruction over a period of days or even weeks, and rarely hours. Hyper-responsiveness of the airways to physical, chemical, and pharmacologic stimuli is a hallmark of asthma.[3] BHR also occurs in some patients with chronic bronchitis and allergic rhinitis.[3] Normal healthy subjects may also develop a transient BHR after viral respiratory infections or ozone exposure. However, the degree of BHR in patients with asthma is quantitatively greater than in other populations. Bronchial responsiveness of the general population fits a unimodal distribution that is skewed toward increased reactivity; individuals with clinical asthma represent the extreme end of this distribution. The degree of BHR within asthma correlates with its clinical course and medication requirement necessary to control symptoms.[3] Patients with mild symptoms or in remission demonstrate lower levels of BHR. The current understanding is that the BHR seen in asthma is at least in part due to and correlative with the extent of airway inflammation.[9]

Factors Contributing to Asthma Severity and Persistence

Viral Respiratory Infections

Viral respiratory infections are primarily responsible for exacerbations of asthma, particularly in children younger than 10 years.[15] Children aged 5 years or younger may have wheezing (which may or may not be asthma) associated with upper respiratory tract infections.[2] Infants are particularly susceptible to airway obstruction and wheezing with viral infections because of their small airways. Approximately 30% to 40% of infants who have severe RSV bronchiolitis will have recurrent wheezing but the subsequent prevalence of asthma is 5% to 10% in children.[15] The most common cause of exacerbations in both children and adults is the rhinovirus, which is the most frequent virus associated with the common cold and distributed worldwide.[15] Other viruses isolated include RSV, parainfluenza virus, adenoviruses, coronavirus, and influenza viruses. Certain viruses (RSV and parainfluenza virus) are capable of inducing specific IgE antibodies, and rhinovirus can activate eosinophils directly in asthmatics.[15] The increase in asthma symptoms and BHR that occurs may last for days or weeks following the resolution of the symptoms of the viral infection. Evidence does not support a beneficial effect of the influenza vaccine for preventing asthma exacerbations from subsequent influenza infections.[3] However, patients with moderate-to-severe asthma should be vaccinated against influenza annually.[31]

Coronavirus Disease (COVID-19)

Asthma does not appear to predispose patients with asthma or make them at increased susceptibility to COVID-19 infection. Nor does it increase the risk of severe infection or death.[12] However, the epidemiology of COVID-19 infection and its relationship to pre-existing conditions, such as asthma, is continuing to be explored as new data emerge. Nonetheless, the use of oral corticosteroids, which are used for the treatment of an asthma exacerbation and severe chronic asthma, may increase the risk of death from COVID-19.[12] Patients who have severe asthma requiring long-term daily oral corticosteroids should not discontinue treatment abruptly due to the risk of serious withdrawal symptoms and even death resulting from long-term adrenal gland suppression. Other treatments for severe asthma such as biologics or immunosuppressants may need to be considered if oral corticosteroids are tapered and discontinued under the supervision of their provider.

Some data indicate that patients who used inhaled corticosteroids (ICS) chronically to treat asthma and were hospitalized with COVID-19 had a lower risk of death than those without an underlying respiratory disease.[12] Therefore, patients should continue their prescribed inhaled ICS if they become infected with COVID-19. It may be difficult to distinguish symptoms of worsening asthma induced by a viral respiratory infection versus COVID-19 symptoms; therefore, an asthma action plan should be instituted or reinforced.

For patients who become infected with COVID-19 and who use a nebulizer for delivery of asthma medications, every effort should be made to transition the patient to an inhaler with a valved spacer and tight-fitting face mask if appropriate. Nebulizers can transmit respiratory viral particles for at least 1 m from the patient which places others at risk of infection.[12] Importantly, inhalers and spacers should not be shared between patients, and spacers should be regularly cleaned and disinfected.

Patients with asthma should be encouraged to receive a COVID-19 vaccination. There are no data to indicate an increased risk of adverse effects in patients with asthma who are vaccinated.[12] However, vaccinations should be administered in a setting where treatment of anaphylaxis is available. Those who have a history of severe allergic reactions to polyethylene glycol or other vaccine ingredients should not be vaccinated with the Pfizer/BioNTech or Moderna vaccines. Biologic drugs used for the treatment of asthma should not be administered on the same day as the COVID-19 vaccination simply to distinguish any emergent adverse effects between the two medications.[12] Patients with asthma can receive the annual influenza vaccination concurrently with the COVID-19 vaccination.

Environmental and Occupational Factors

The development and heterogeneity of persistent asthma are driven by complex gene-environment interactions. Agents and events that are known to trigger asthma are listed in Table 44-1. The mechanisms for inducing symptoms are as varied as the exposure factor and include both IgE- and cell-mediated reactions.[31] The World Allergy Organization (WAO) predicts an increase in the incidence and prevalence of asthma due to environmental exposures from climate change.[32] Greater temperature variability, industrial pollution, more frequent forest fires, a higher concentration of ground-level ozone, increased transboundary movement of respiratory infectious agents, and changes in aeroallergen distribution are all cited factors. Sulfur dioxide in the ambient atmosphere is highly irritating and presumably induces bronchoconstriction through mast cell or irritant-receptor involvement.[33] Asthma produced by repeated prolonged exposure to industrial inhalants is a significant health problem. It has been estimated that 25% of adult-onset asthma worldwide is occupationally related.[33] Occupational asthma can be difficult to diagnose as the latency between exposure and symptom development can extend from months to years.[33] Persons with occupational asthma have the typical symptoms of asthma with cough, dyspnea, and wheezing. Typically, the symptoms are related to workplace exposure and improve on days off and during vacations.[33] Once occupational asthma has developed, the symptoms persist in most patients even after exposure is no longer present.[33]

TABLE 44-1

List of Agents and Events Triggering Asthma Exacerbations

Respiratory infection	Respiratory syncytial virus (RSV), rhinovirus, coronavirus, influenza, parainfluenza, *Mycoplasma pneumonia*, *Chlamydia*, chronic rhinosinusitis
Allergens	Airborne pollens (grass, trees, weeds), house dust mites, animal dander, rodents, cockroaches, fungal spores
Environment	Cold air, fog, ozone, sulfur dioxide, nitrogen dioxide, tobacco smoke (including second and third hand), wood smoke, energy-efficient buildings (increase indoor air pollution), meteorological conditions related to climate change, scented home products, cleaners, and perfumes
Emotions	Anxiety, stress, laughter
Exercise	Particularly in a cold, dry climate
Drugs/preservatives	Acetaminophen, Aspirin, NSAIDs (cyclooxygenase inhibitors), sulfites, benzalkonium chloride, nonselective β-blockers, higher airway reversibility to β_2-agonist
Occupational stimuli	Bakers (flour dust); farmers (hay mold); spice and enzyme workers; occupational cleaners, printers (Arabic gum); chemical workers (azo dyes, anthraquinone, ethylenediamine, toluene diisocyanates, polyvinyl chloride); plastics, rubber, and wood workers (formaldehyde, western cedar, dimethylethanolamine, anhydrides)
Host factors	Obesity, African American race, Hispanic ethnicity, low socioeconomic status

Stress, Depression, and Psychosocial Factors

Observational studies demonstrate an association between increased stress and worsening asthma, but the role is not clearly defined.[3] Bronchoconstriction from psychological factors is mediated primarily through excess parasympathetic input. Atropine has been shown to block experimental psychogenic bronchoconstriction. Persons with asthma are more likely to have depression than those without asthma. The episodic nature of both diseases may be related to abnormal expression of Th2 cytokines that have effects in the brain as well as the airway. It is most important to emphasize to both patients and parents of children with asthma that asthma is not an emotional disease. However, coping skills may benefit the patient who becomes emotionally distraught during an asthma exacerbation.

Chronic Rhinosinusitis

Disorders of the upper respiratory tract, particularly rhinitis and sinusitis, have been linked with asthma. The prevalence of allergic sensitization increases with asthma severity; nasal polyposis is often seen in those with allergic rhinitis. It has been postulated that the transport of mucus chemotactic factors and inflammatory mediators from nasal passages during allergic rhinitis into the lungs may accentuate BHR. However, chronic sinusitis may just represent a nonbacterial coexisting condition in patients with asthma and allergies because the histologic changes in the paranasal sinuses are similar to those seen in the lung and nose. Thus, it would seem that treatment of rhinosinusitis could improve asthma control. However, a large study of children and adults found that treatment of chronic sinonasal disease with intranasal corticosteroids for 6 months improved neither asthma control nor BHR, suggesting that the treatment of sinus disease and asthma should be separately managed.[12]

Gastroesophageal Reflux Disease

Symptoms of gastroesophageal reflux disease (GERD), as well as asymptomatic reflux, are common in both children and adults who have asthma.[12] Nocturnal asthma may be associated with nighttime reflux. Reflux of acidic gastric contents into the esophagus is thought to initiate a vagally mediated reflex bronchoconstriction. Also of concern is that most medications that decrease airway smooth muscle tone have a relaxant effect on gastroesophageal sphincter tone. There is no benefit from screening or treating asymptomatic reflux in patients with asthma (Evidence A).[12] However, for patients who have asthma and symptoms of reflux, a trial of anti-reflux medication may improve reflux symptoms; if there is no resolution, further evaluation is warranted.[12] Treatment with proton pump inhibitors does not improve asthma control even in those with documented reflux.[12]

Microbiome

As the role of microbes in human health and disease continues to unfold, there is an increased investigation into the airway and gastrointestinal microbiome's relationship to asthma.[34] Patients with asthma and other obstructive lung diseases have shown differences in the lower airway microbiome compared with healthy individuals.[34] Evidence suggests that treatment-resistant asthma and worse lung function of select patients may be correlated to microbiota differences in the sputum. The upper airway microbiome has different microbiota than the lower airway by which pressure and temperature changes favor certain bacterial populations.[34] In a population-based study following infants to children, those with an altered nasal microbiota (eg, persistent *Moraxella* sparsity) were found to be at higher risk for developing asthma.[35] The gut microbiota is better studied and correlates to the risk of allergic sensitization and infant response to viral respiratory tract infections. As these relationships of the microbiome are further studied, the potential for developing strategies for the prevention and development of asthma may be possible.

Female Hormones

Asthma symptoms may vary significantly during different stages of the menstrual cycle. Premenstrual worsening of asthma symptoms has been reported in 20% of women and worsening of pulmonary function has been observed in women who do not report worsening symptoms.[36] Women with premenstrual symptoms tend to be older, have a higher body mass index, more severe asthma, aspirin sensitivity, and a longer duration of asthma.[36] The pathophysiology is uncertain because estrogen replacement in postmenopausal women has been shown to worsen asthma, whereas estradiol and progesterone administration has been reported to both improve or have no effect on asthma in women with premenstrual asthma.[36] Some studies have reported an increase in ED visits by women who were premenstrual, whereas others have reported no association with the menstrual phase.[36] Pregnancy may cause worsening, improvement, or no change in asthma symptoms, and the changes seem to occur with equal frequency.[36]

Foods, Additives, Supplements, and Vitamins

Food chemicals, specifically sulfites used as preservatives, can trigger life-threatening asthma exacerbations. Beer, wine, dried fruit, and open salad bars, in particular, have high concentrations of metabisulfites.[3] Food avoidance is only recommended when there is clear documentation of allergy or food chemical sensitivity.[12]

Aspirin and other nonsteroidal anti-inflammatory drugs can cause severe asthma exacerbations (aspirin-exacerbated respiratory disease).[12] The mechanism is related to cyclooxygenase-1 (COX-1) inhibition. Inhaled corticosteroids (ICSs) are the primary preventive treatment although oral corticosteroids may be required; leukotriene receptor antagonists (LTRAs) may be useful.[12] Aspirin sensitivity occurs in 7% of adults with asthma and is associated with a more severe disease.[12] While nonselective β-blocking agents do not precipitate bronchospasm, they can prevent reversal.

Vitamin D supplementation may be beneficial to reduce asthma exacerbations in patients who require oral corticosteroids and have low 25-hydroxyvitamin D plasma concentrations (<10 ng/mL [25 nmol/L]).[12] However, high-quality studies confirming improvements in asthma control or reductions in exacerbations are lacking.[12]

The impact of the maternal diet on allergy and asthma development has been a research focus of interest. In a systematic review, fish oil supplementation or dietary intake of fish during pregnancy had no consistent effects on the risk of wheeze, asthma, or atopy in the child.[12] Some evidence indicates that maternal intake of peanut and milk products are associated with decreases in allergy and asthma in the offspring. Due to limited evidence, dietary changes during pregnancy are not recommended now.

Obesity

Epidemiologic data suggest that obesity increases the prevalence of asthma and may reduce asthma control, although it is difficult to distinguish obesity-induced respiratory symptoms from true asthma symptoms because obesity often precedes the onset of asthma. Lung volume and tidal volume are reduced in obesity, promoting airway narrowing. Obesity also produces low-grade systemic inflammation that may act on the lung to worsen asthma. The mechanism may include the release of adipose-derived pro-inflammatory mediators such as IL-6, IL-10, eotaxin, tumor necrosis factor-α, transforming growth factors-β_1, C-reactive protein, leptin, and adiponectin or a result of common predisposing dietary factors. Being overweight or obese is a risk factor for childhood asthma, particularly in females; conversely, there is no evidence that having asthma increases the risk for obesity.[12]

Exposure to Tobacco Smoke and COPD Overlap

A thorough history that considers age, respiratory symptoms, past medical history, previous diagnoses, and treatments, as well as social and occupational risk factors, may identify relevant a smoking history or exposure to environmental tobacco smoke. The clinician is then faced with distinguishing asthma from COPD. First termed *asthma COPD overlap syndrome* (ACOS) and more recently *asthma COPD overlap* (ACO), some patients have clinical features of both asthma and COPD.[37] Physical examination findings, lung function measures, and radiology data are then combined with the history to confirm this syndromic diagnosis. GINA and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) provide recommendations for initial therapy of ACO if the diagnostic features are equally balanced between asthma and COPD.[37] However, GOLD no longer refers to ACOS due to a misperception that ACOS is a distinct disorder. Rather, GOLD emphasizes that asthma and COPD are different disorders with common traits and features and may coexist in the same patient. Given that patients with features of both asthma and COPD are most often excluded from clinical studies, the pathophysiology and treatment remain less defined for these patients. Compared to patients with either asthma or COPD alone, those with ACO have a greater symptom burden, physical impairment, and hospitalizations with worse quality of life.[38] The origins of ACO may begin in childhood regardless of smoking history, but smoke may have more severe effects on lung function in patients with asthma. Referral for expert advice and further diagnostic evaluation for ACO patients may be necessary. GOLD recommends clinicians prioritize asthma treatment for patients with ACO.[37]

CLINICAL PRESENTATION

Chronic Asthma

③ Classically, asthma is characterized by episodic and variable respiratory symptoms; however, the clinical presentation of asthma is as diverse as the number of triggering events (see “Clinical Presentation: Chronic Asthma”). Although wheezing is the characteristic symptom of asthma, the medical literature is replete with the warning that “not all that wheezes is asthma.” A wheeze is a high-pitched, whistling sound created by turbulent airflow through an obstructed airway, so any condition that produces significant obstruction can result in wheezing as a symptom. In addition, “all of asthma does not wheeze” is an equally justifiable warning. Patients may present with a chronic persistent cough (cough variant asthma) as their only symptom.[12]

There is no single diagnostic test for asthma. The diagnosis is based primarily on a thorough history gathered from the patient.[12] The patient may have a family history of allergy or asthma or have symptoms of allergic rhinitis, or atopic dermatitis. Reversibility of airway obstruction following administration of a SABA or excessive variability in twice-daily peak expiratory flow (PEF) over 1 to 2 weeks are diagnostic criteria. Patients with normal spirometry values can be challenged with exercise or substances that produce bronchoconstriction, such as methacholine or mannitol, to determine if they have BHR, but again, a positive challenge test is not diagnostic. Newer tests of inflammation in the airways such as induced sputum eosinophil and neutrophil counts or FeNO measurements are consistent with but not diagnostic of asthma. According to the 2020 Asthma Focused Updates, when the diagnosis is uncertain, a FeNO is recommended as an adjunctive diagnostic test.[11] FeNO results should be interpreted in conjunction with other conditions or factors that influence FeNO levels in patients with asthma (eg, smoking, obesity, and corticosteroid use are associated with lower levels whereas atopy, eosinophilic bronchitis is associated with higher levels).

GINA recommends confirmation of the diagnosis of asthma in patients already taking controller treatment using objective testing. The process depends on the patient's symptoms and lung function and may include a trial of either a lower or a higher dose of controller treatment.[12]

The frequency and severity of asthma symptoms vary widely. The intervals between symptoms can be days, weeks, months, or years. Asthma also can vary in its severity and is related to the intrinsic intensity of the disease process. Asthma severity is determined by lung function, symptoms, nighttime awakenings, rescue SABA use, interference with normal activity prior to therapy, and frequency of exacerbations requiring systemic corticosteroids.[39] Severity is most easily and directly measured in a patient who is not currently receiving asthma treatment. The NAEPP has provided a means of classifying asthma severity that is divided into two domains: impairment and risk.[3] This classification system is individualized for three age groups (0-4, 5-11, and greater than or equal to 12 years) and summarized in Table 44-2. Based on these domains, an individual's severity category is based on the greatest level of either impairment or risk. For example, a patient with several features consistent with mild persistent severity but who has one feature in the moderate persistent category is classified as having moderate persistent asthma. Although classifying severity is helpful for determining the initial treatment, subsequent management is determined by the level of symptom control. GINA has provided a slightly different framework for determining chronic therapy for children and adults based on symptom control and future risk of adverse outcomes.[12]

TABLE 44-2

Classifying Asthma Severity for Patients Who Are Not Currently Taking Long-Term Control Medications

	Children 0-4 and 5-11 Years of Age				
	Persistent				
	Components	**Intermittent**	**Mild**	**Moderate**	**Severe**
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings (0-4 years)	0	1-2 × month	3-4 × month	>1 × week
	Nighttime awakenings (5-11 years)	≤2 × month	3-4 × month	>1 × week, but not nightly	Often 7 × week
	SABA use for symptom control	≤2 days/wk	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	$FEV_1 > 80\%$	$FEV_1 > 80\%$	FEV_1 60%-80%	$FEV_1 < 60\%$
	5-11 years	FEV_1/FVC >85% (0.85)	FEV_1/FVC >80% (0.80)	FEV_1/FVC 75%-80% (0.75-0.80)	FEV_1/FVC <75% (0.75)
	Exacerbations	**Intermittent**	**Persistent**		
Risk	0-4 years	0-1/year	≥2 in 6 months or ≥4 wheezing episodes/1 year lasting >1 day		
	5-11 years	0-2/year	>2 in 1 year		

	Recommended initial treatment	Step 1	Step 2	Step 3 and consider short-course of oral corticosteroids	
		Youths ≥12 Years of Age and Adults			
			Persistent		
	Components	**Intermittent**	**Mild**	**Moderate**	**Severe**
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2 × month	3-4 × month	>1 × week, but not n ightly	Often 7 × week
	SABA use for symptom control	≤2 days/week	>2 days/week, but not >1 × day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	FEV_1 > 80%	FEV_1 > 80%	FEV_1 60%-80%	FEV_1 < 60%
		[a]FEV_1/FVC normal	[a]FEV_1/FVC normal	[a]FEV_1/FVC reduced 5% (0.05)	[a]FEV_1/FVC reduced > 5% (0.05)
	Exacerbations	Intermittent	Persistent		
Risk		0-2/year	>2 in 1 year		
	Recommended initial treatment	Step 1	Step 2	Step 3 and consider short course of oral corticosteroids	Step 4 or 5 and consi der course of oral co rticosteroid

SABA, short-acting β-agonist.

[a]Normal FEV_1/FVC: 8 to 19 years 85% (0.85); 20 to 39 years 80% (0.80); 40 to 59 years 75% (0.75); 60 to 80 years 70% (0.70).

The frequency or chronicity of the symptoms is not necessarily associated with the severity of symptoms during exacerbations. Patients can present with a range from intermittent symptoms that require no medications or only occasional SABA use to severe persistent asthma symptoms despite treatment with multiple medications.

CLINICAL PRESENTATION: Chronic Asthma

General

- Asthma is a disease of exacerbation and remission, so the patient may not have any signs or symptoms at the time of examination.

Symptoms

- The patient may complain of episodes of shortness of breath, chest tightness, coughing (particularly at night), wheezing, or a whistling sound from the chest when breathing. These often occur in association with exercise, but also occur spontaneously or in association with known allergens.

Signs

- Wheezing on auscultation (more typically on expiration), prolonged expiratory phase on auscultation dry hacking cough or signs of atopy (allergic rhinitis and/or atopic dermatitis) may occur.

Laboratory

- Spirometry demonstrates obstruction (reduced FEV_1/forced vital capacity [FVC]) with reversibility following inhaled β_2-agonist administration (FEV_1 increases by more than 12% and 200 mL). The FEV_1/FVC ratio is normally more than 75% to 80% (0.75 - 0.80) in adults and more than 85% (0.85) in children.

Other diagnostic tests

- Excessive variability in twice-daily peak expiratory flow (PEF) over 2 weeks (greater than 10% in adults and greater than 13% in children). A fall in FEV_1 of at least 10% following 6 minutes of near-maximal exercise. Elevated eosinophil count and IgE concentration in blood. FeNO less than 20 ppb in children younger than 12 years and less than 25 ppb in adults suggest a diagnosis other than asthma. Positive methacholine challenge (PC20 FEV_1 less than 12.5 mg/mL) or mannitol challenge (FEV_1 decrease of at least 15% from baseline after 635 mg or less).

Acute Severe Asthma

Uncontrolled asthma, with its inherent variability, can progress to an acute state where inflammation, airway edema, excessive mucus accumulation, and severe bronchospasm result in a profound airway narrowing that is poorly responsive to usual bronchodilator therapy (see "Clinical Presentation: Acute Severe Asthma").[40] Although this progression is a common scenario, some patients experience rapid-onset or hyper-acute exacerbations.[40] Hyper-acute exacerbations are associated with neutrophilic as opposed to eosinophilic infiltration and resolve rapidly with bronchodilator therapy, suggesting that smooth muscle spasm is the major pathogenic mechanism.[40] In most cases, emergency department (ED) visits for acute severe asthma represent the failure of an adequate therapeutic regimen to control persistent asthma. Underutilization of anti-inflammatory drugs and excessive reliance on SABA are the major risk factors for severe exacerbations.[40] However, frequent exacerbations may represent a specific phenotype of asthma. A blunted perception of airway obstruction may predispose certain individuals to fatal asthma attacks.[40]

CLINICAL PRESENTATION: Acute Severe Asthma

General

- Although an episode can progress over several days or hours (usual scenario), it can progress rapidly over 1 to 2 hours.

Symptoms

- The patient is anxious in acute distress and complains of severe dyspnea, shortness of breath, chest tightness, or burning. The patient is only able to say a few words with each breath. Symptoms are unresponsive to usual measures (short-acting inhaled β_2-agonist administration).

Signs

- Signs include expiratory and inspiratory wheezing on auscultation (breath sounds may be diminished with very severe obstruction), dry hacking cough, tachypnea, tachycardia, pale or cyanotic skin, hyper-inflated chest with intercostal and supraclavicular retractions, and hypoxic seizures if very severe.

Laboratory tests

- Peak expiratory flow and/or FEV_1 less than 40% of normal predicted values. Decreased arterial O_2 (PaO_2), and O_2 saturations by pulse oximetry (SaO_2 less than 90% [0.90] on room air is severe). Decreased arterial or capillary CO_2 if mild, but in the normal range or increased in moderate-to-severe obstruction.

Other diagnostic tests

- Blood gases to assess metabolic acidosis (lactic acidosis) in severe obstruction. Complete blood count if there are signs of infection (fever and purulent sputum). Serum electrolytes as therapy with β_2-agonist and corticosteroids can lower serum potassium, magnesium, and phosphate, and increase glucose. Chest radiograph if signs of consolidation on auscultation.

Exercise-Induced Bronchospasm

During vigorous exercise, pulmonary function measurements (FEV_1 and PEF) in patients with asthma increase during the first few minutes but then begin to decrease after 6 to 8 minutes.[2] Exercise-induced bronchospasm (EIB) is defined as a drop in FEV_1 of 10% or greater from baseline (pre-exercise value).[2] Most studies suggest that many patients with persistent asthma experience EIB.[3] The exact pathogenesis of EIB is unknown, but heat loss and/or water loss from the central airways play an important role.[41] EIB is provoked more easily in cold, dry air, ambient ozone, and airborne particulate matter; alternatively, warm, humid air can blunt or block it.[42] Studies have demonstrated increased plasma histamine, cysteinyl LTs, prostaglandins, and tryptase concentrations during EIB, suggesting a role for mast cell degranulation.[41] These findings led to the development of inhaled mannitol, an osmotic agent, as an indirect pharmacologic bronchoprovocation test to assist in the diagnosis of asthma.

A refractory period following EIB lasts up to 4 hours after exercise in some patients. The refractory period is thought to be caused by an acute depletion of mast cell mediators and the time required for their repletion.

EIB is believed to be a reflection of increased BHR associated with asthma. A correlation, though not perfect, exists between EIB and reactivity to histamine, methacholine, and mannitol. During periods of remission, a decreased sensitivity to the same degree of exercise is often observed. Many children and adults with EIB report no symptoms and have normal pulmonary function except in association with exercise.[2] Interestingly, elite athletes have a higher prevalence of EIB than the general population.[41]

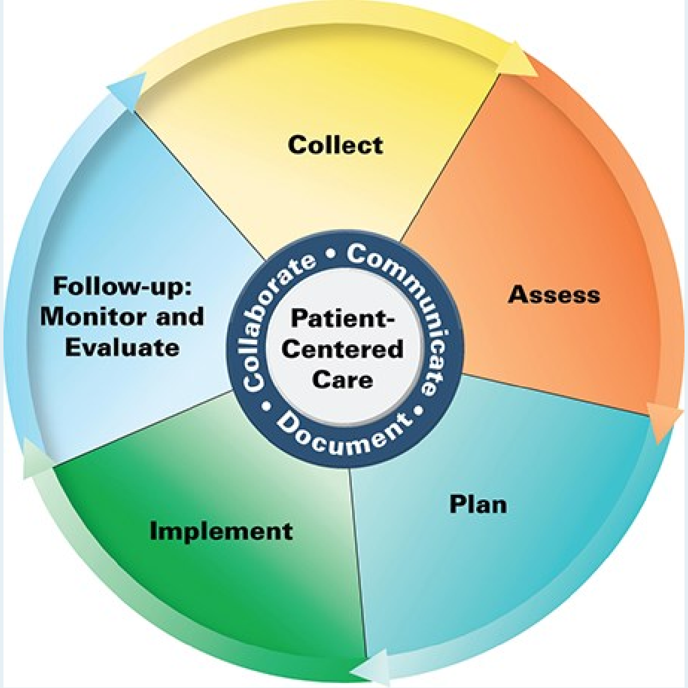
Nocturnal Asthma

3 Worsening of asthma during sleep is referred to as *nocturnal asthma*. Patients with nocturnal asthma have significant declines in pulmonary function between bedtime and awakening.[2] Typically, their lung function reaches a nadir at 3 to 4 AM. Although the pathogenesis of this phenomenon is unknown, it has been associated with diurnal patterns of endogenous cortisol secretion and circulating epinephrine and is associated with an increase in airway inflammation.[2]

Numerous other factors may affect nocturnal worsening of asthma, including allergies and improper environmental control, gastroesophageal reflux, obstructive sleep apnea, and sinusitis. Experts consider nocturnal symptoms to be a sign of inadequately treated persistent asthma. Awakening from nocturnal asthma is a sensitive indicator of both severity and inadequate control.

PATIENT CARE PROCESS

Patient Care Process for the Management of Persistent Asthma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race/ethnicity, sex, pregnancy status)
- Patient history (eg, past medical, known triggers, psychosocial history, gastroesophageal reflux disease)
- Family history (eg, asthma, allergy, atopic dermatitis)
- Home/work environment (eg, environmental, occupational, tobacco smoke, carpet/bedding, pets) (see Table 44-1)
- Current medications and prior response to controller therapies (eg, ICS+/−LABA; montelukast; LAMA; biologic therapies)
- Subjective and objective data (see Table 44-2)
    - Symptoms (description and frequency)
    - Nocturnal awakenings
    - Albuterol use frequency for symptom control

  - Activity limitation
  - Exacerbation frequency
  - Peak expiratory flow readings

Assess

- Comorbid conditions (eg, allergies, rhinosinusitis, obesity, obstructive sleep apnea, gastroesophageal reflux, smoking)
- Symptom frequency including exercise tolerance (see Tables 44-2)
- Exacerbation history (eg, oral corticosteroid use, emergency department visits, hospitalization)
- Current medications that may contribute to or worsen asthma (eg, nonsteroidal anti-inflammatory drug [NSAID], aspirin) (see Table 44-1)
- Appropriateness and effectiveness of current medications in controlling symptoms and preventing exacerbations
- Inhaler technique (see Fig. 44-10) and adherence; potential barriers
- Socioeconomic barriers to obtaining medications
- Adherence to nonpharmacologic recommendations (eg, allergen avoidance, environmental control)

Plan*

- Tailored environmental modifications (eg, pet removal, carpet removal, pillow and mattress covers, exercise pretreatment, occupational exposures) (see Table 44-1)
- Medication therapy regimen: dose, route, frequency, duration, and MDI spacer; specify the continuation and discontinuation of existing therapies (see Tables 44-4, 44-7, 44-8, 44-10, and 44-13)
- Monitoring parameters include efficacy (eg, daily symptoms, nocturnal awakenings, albuterol use, exercise tolerance, peak expiratory flow [in selected patients]), and time frame (see Table 44-2)
- Patient/family education (eg, purpose of treatment, environmental modifications, drug therapies, inhaler technique)
- Self-monitoring of symptoms, albuterol use, peak expiratory flow (in selected patients)—where and how to record results (see Fig. 44-6)
- Referrals to other providers when appropriate (eg, specialist physician)

Implement*

- Provide patient/family education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up based on symptoms and medication changes

Follow-up: Monitor and Evaluate

- Determine symptom control and exacerbation outcomes
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcomes

GINA's long-term goals for asthma management are: (1) to achieve good control of symptoms and maintain normal activity levels and (2) to minimize future risk of exacerbations, fixed airflow limitation, and medication-related side effects.[12] The importance of eliciting the patient's own goals is critical through an ongoing patient-healthcare provider partnership. Key components are strategies to facilitate effective communication and reduce the impact of impaired health literacy.[12] Self-management education reduces asthma morbidity in both adults and children (Evidence A).[12] GINA and NAEPP recommend control-based asthma management, adjusting pharmacological and nonpharmacological treatment in a continuous cycle of assessment, treatment adjustment, and review. Assessment includes symptom control, risk factors, inhaler technique and adherence, and patient preferences. Response review includes symptoms, exacerbations, medication side effects, patient satisfaction, and lung function.[11,12]

GINA differentiates between the preferred treatment options at a population level (based on efficacy, effectiveness, safety, availability, and cost) versus appropriate treatment options for individual patients. A shared decision-making approach is recommended and should include a discussion of preferred treatment options, patient characteristics or phenotype, patient/parent preferences, and practical issues (inhaler technique, adherence, and cost).[12] Evidence suggests that a shared decision-making approach may be associated with better outcomes.[12]

General Approach to Treatment

The NAEPP[3,11] and GINA[12] outline sound strategies for the management and treatment of asthma. The NAEPP EPR3 guideline was last published in 2007 and updated in 2020. The NAEPP 2020 Asthma Focused Updates specifically reviewed six topics for clinical management of asthma, but did not comprehensively revise the 2007 EPR3.[11] Therefore, health care professionals may need to use both the EPR3 and 2020 Focused Updates when managing a patient with asthma.

The GINA guidelines and the 2020 Asthma Focused Updates use different approaches in evaluating the literature and determining recommended treatment approaches. The NAEPP continues to utilize the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach, an internationally accepted framework to determine the strength of a recommendation, however, is generally less nimble for incorporating new evidence. The GINA guidelines are updated every year, and thus, GINA is generally more current and can indicate emerging treatment strategies.[12] Thus, clinicians may consult both guidelines for these reasons. With the release of the 2020 Asthma Focused Updates, the GINA and the NAEPP overall guidance have become more similar and will be described in further detail for the management of chronic asthma.

General Approach to the Management of Chronic Asthma

As outlined in the 2020 Asthma Focused Updates, a stepped approach to managing persistent asthma is used for all ages (Fig. 44-3–44-5)[11]. Step of care depends upon whether the individual is newly diagnosed (treatment naïve) or if therapy is being adjusted to achieve control. If newly diagnosed, the initial step is based upon levels of impairment and risk which determine asthma severity (Table 44-2)[39]. All patients with persistent asthma (mild, moderate, or severe) should also be initiated on inhaled corticosteroid therapy. ⑤ An ICS is the preferred long-term controller therapy for persistent asthma in all patients due to potency and consistent effectiveness.[11,12] ICSs reduce BHR, improve lung function, and reduce severe exacerbations leading to ED visits and hospitalizations. ICS therapy is more effective than theophylline or the LTRAs. In addition, ICS therapy is the only treatment that has been documented to reduce the risk of dying from asthma.[11,12] Therapy is escalated as needed by increasing the dose of ICS or the addition of a second and then a third inhaled controller medication, typically a long-acting β_2- adrenergic receptor agonist (LABA) (preferred choice) or a long-acting muscarinic agonist (LAMA) (Fig. 44-3–44-5). All patients with asthma should have quick-relief medication (reliever therapy), available for acute symptoms. It is important to ensure that the patient can correctly use both the reliever and controller delivery devices. Once therapy has been initiated, patients are then evaluated 2 to 6 weeks later to rate their level of control (ie, well-controlled, not well controlled, or very poorly controlled) using the same domains of impairment and risk in severity classification.[39] Based on their level of control, step therapy should be adjusted accordingly and follow-up should continue every 2 to 3 months as indicated by clinical urgency.

FIGURE 44-3

Stepwise approach for management of asthma in ages 0 to 4 years. (ICS, inhaled corticosteroids; LABA, long-acting β_2-agonist; SABA, inhaled short-acting β_2-agonist; RTI, respiratory tract infection; PRN, as needed.) [a]Updated based on the 2020 guidelines. [b]Cromolyn and montelukast were not considered for this update and/or have limited availability for use in the United States. The Food and Drug Administration (FDA) issued a Boxed Warning for montelukast in March 2020. (*Data from Reference 11*.)

	Intermittent Asthma	Management of Persistent Asthma in Individuals Ages 0–4 Years				
Treatment	**STEP 1**	**STEP 2**	**STEP 3**	**STEP 4**	**STEP 5**	**STEP 6**
Preferred	PRN SABA and At the start of RTI: Add short course daily ICS▲	Daily low-dose ICS and PRN SABA	Daily medium-dose ICS and PRN SABA	Daily medium-dose ICS-LABA and PRN SABA	Daily high-dose ICS-LABA and PRN SABA	Daily high-dose ICS-LABA + oral systemic corticosteroid and PRN SABA
Alternative		Daily montelukast* or Cromolyn,* and PRN SABA		Daily medium-dose ICS + montelukast* and PRN SABA	Daily high-dose ICS + montelukast* and PRN SABA	Daily high-dose ICS + montelukast*+ oral systemic corticosteroid and PRN SABA
			For children age 4 years only, see Step 3 and Step 4 on Management of Persistent Asthma in Individuals Ages 5–11 Years diagram.			

Assess Control

- First check adherence, inhaler technique, environmental factors,▲ and comorbid conditions.
- **Step up** if needed; reassess in 4–6 weeks
- **Step down** if possible (if asthma is well controlled for at least 3 consecutive months)

Consult with asthma specialist if Step 3 or higher is required. Consider consultation at Step 2.

Control assessment is a key element of asthma care. This involves both impairment and risk. Use of objective measures, self-reported control, and health care utilization are complementary and should be employed on an ongoing basis, depending on the individual's clinical situation.

Consult with asthma specialist if Step 4 or higher is required. Consider consultation at Step 3.

Control assessment is a key element of asthma care. This involves both impairment and risk. Use of objective measures, self-reported control, and health care utilization are complementary and should be employed on an ongoing basis, depending on the individual's clinical situation.

The primary therapeutic differences between GINA and the 2020 Asthma Focused Updates are in Steps 1 and 2 therapy for adolescents and adults. For adolescents and adults, Step 1 therapy in the 2020 Asthma Focused Updates begins with as-needed rescue therapy (ie, SABA). Step 2 progresses to adding a controller therapy of low-dose ICS or as needed concomitant ICS and SABA. GINA, on the other hand, recommends the use of ICS-formoterol taken as-needed in Steps 1 and 2. Both guidelines recommend the use of ICS-formoterol therapy for maintenance and as-needed use, known as Single Maintenance And Reliever Therapy (SMART) as the preferred therapy, for Steps 3 and 4 in patients aged 4 years[11] or 6 years[12] and older. Add-on LAMA with ICS-LABA (2020 Asthma Focused Updates) or SMART (GINA) is recommended for Step 5 in patients 12 years and older.

When asthma remains poorly controlled with ICS-LABA with LAMA or SMART with LAMA, the addition of biologics can be considered.[11,12] There are currently no studies that support the selection of one biologic over another other than by criteria included in the labeling (eg, serum IgE or eosinophil levels).

SMART therapy reduces exacerbation rates and corticosteroid use but has inconsistent effects on asthma control and quality of life.[11] SMART therapy has only been used with formoterol as the LABA component due to its rapid onset of action and maximum allowable total daily dose. The maximum formoterol dose in children aged 4 to 11 years for SMART is eight inhalations of 4.5 μg/inhalation (total dose 36 μg formoterol). Budesonide was the inhaled corticosteroid studied in this age group. In patients aged 12 years and older, the SMART maintenance dose is one to two puffs once or twice daily plus a rescue dose of one to two puffs as needed up to a combined maximum of 12 puffs per day (total dose 54 μg formoterol). Importantly, ICS-formoterol reliever therapy is not to be used concomitantly with ICS-salmeterol maintenance therapy.[11,12]

Although the alternative long-term control therapies (eg, LTRAs and theophylline), used as either monotherapy or concomitantly with ICS, improve symptoms, lung function, and reduce as-needed SABA use, they do not reduce BHR, suggesting minimal anti-inflammatory activity.[11,12] There are minimal to no differences in efficacy between these alternatives.

Other therapies reserved for the treatment of uncontrolled severe asthma after an optimal trial of high-dose ICSs in combination with LABA or LAMA or biologic therapy include bronchial thermoplasty and oral corticosteroids. The GINA guidelines also suggest considering treatment with azithromycin for its anti-inflammatory effects in adults whose asthma is uncontrolled despite higher doses of ICS-formoterol.[12] Due to significant adverse effects that occur with their long-term use, oral corticosteroids are prescribed at the lowest dose that maintains asthma control and administered daily or every other day. Bronchial thermoplasty reduces the airway smooth muscle mass by targeting the hypertrophied smooth muscle in the airways and delivers thermal energy in a controlled manner to the airway wall. This results in a reduced response to bronchoconstrictive stimuli. Bronchial thermoplasty is not recommended in the 2020 Asthma Focused Updates due to the relatively small improvements in asthma control and the moderate risk of harm observed in clinical trials. Moreover, there is an insufficient long-term follow-up in large numbers of patients to adequately assess its benefits and harms.[11] Both guidelines recommend a very careful selection of patients before using bronchial thermoplasty.

Patients with documented allergen sensitization with clinical symptoms can be considered for allergen immunotherapy, given either by subcutaneous injections or sublingually. The 2020 Asthma Focused Updates do not recommend sublingual therapy except in those who also have allergic rhinoconjunctivitis. Data regarding immunotherapy will continue to expand and be reviewed.[11,12] Patients suitable for subcutaneous therapy are those children aged 5 years and older who demonstrate allergic sensitization and adults with allergic asthma who have worsening asthma symptoms temporally related to allergen exposure and who have testing that confirms sensitization. Subcutaneous therapy is not recommended in patients with severe asthma due to the risk of systemic reactions. Subcutaneous treatment must be administered in a setting that is prepared to manage anaphylactic reactions. Sublingual treatment must initially be supervised by health professionals but may be continued at home if there are no systemic adverse effects observed.[11] Because treatment may involve weekly appointments for several years, patients need to carefully consider the burden of treatment before initiating allergy immunotherapy.

GINA provides general principles for stepping-down controller treatments.[12] Step-down therapy is warranted if symptoms have been well controlled and lung function has been stable for at least 3 months (Evidence Grade D). Step-down therapy should only be initiated when the patient is expected to remain stable; for example, at a time when the patient has no evidence of a respiratory infection, will not be traveling, and is not pregnant. When engaging in a trial of treatment step-down, the patient should regularly monitor symptoms and PEF, and a follow-up visit with the provider should be scheduled (Evidence Grade D). Stepping down ICS doses by 25% to 50% at 3-month intervals is considered feasible and safe for most patients (Evidence Grade A).

GINA emphasizes three components of personalized asthma management: ASSESS, ADJUST, and REVIEW RESPONSE.[12] It is important to ASSESS and document symptom control and risk factors at every patient encounter. If symptoms are uncontrolled, check inhaler technique and adherence, and consider whether symptoms are due to a comorbid condition such as allergic rhinitis, GERD, or obesity rather than asthma. ADJUST therapy (intensify or de-escalate)—both drug therapy and nonpharmacological strategies; treat modifiable risk factors. REVIEW RESPONSE—assess and optimize asthma control about every 3 months.

Special Populations

Infants and Children Younger than 5 Years

The management of asthma in children younger than 5 years follows the same stepwise approach as in older children and adults but many treatments have not been studied adequately (Fig. 44-3) Thus, many of the recommendations in this age group are extrapolated from older children and adults.[11,12] Because viral respiratory tract infections are a common cause of wheezing in young children, the 2020 Asthma Focused Updates now recommend starting a short (7-10 day) course of ICS with as-needed SABA at the start of a respiratory tract infection.[11] A suggested regimen is budesonide inhalation suspension, 1 mg, twice daily.[11] The primary differences in chronic management in this age group are that no controller treatment is necessarily indicated for Step 1 and the recommended treatment in Step 3 is doubling the dose of ICS rather than adding LABA as is recommended for older children and adults.[11,12] There is insufficient evidence to recommend ICS-LABA in young children at any step of therapy.[12] Most of the available ICS have been studied in young children but not all have marketing approval from the FDA in this age group. Lack of an approved indication in children younger than 5 years could affect insurance coverage for specific products. ICSs are available as MDI, DPI, and nebulized formulations but the preferred method of delivery is by MDI with a valved spacer and facemask in children younger than 3 years and valved spacer for older children, if needed.[12] Smaller spacers (less than 350 mL) are preferred because 5 to 10 breaths after actuation are required to inhale the complete dose. It is also recommended to not change the spacer type once a child is stable on a specific dose of ICS due to large differences in delivery between devices.[12] ICS use, even with low doses, causes reductions in growth velocity in children who are clinically important.[11,12] Thus, the lowest effective should be used and height should be regularly measured during treatment.[11,12]

The 2020 Asthma Focused Updates now recommends that a short course of daily ICS be initiated at the start of a respiratory tract infection in children who have had three or more episodes of wheezing triggered by presumed respiratory tract infections in their lifetime.[11] Treatment of moderate-to-severe asthma exacerbations may require the use of oral corticosteroids but nebulized budesonide at a dose of 1 mg twice daily for 7 days is effective at preventing exacerbations requiring treatment with oral corticosteroids. This dose did not affect linear growth but higher doses of other ICS (eg, fluticasone 750 µg twice daily for 10 days) may reduce the growth rate.[11] Therefore, the growth rate should be monitored regularly.

The FDA approval for montelukast (an LTRA) in children younger than 6 years was based on safety and pharmacokinetic studies establishing doses but not on efficacy, although improvement in symptoms and as-needed bronchodilators was noted. Montelukast is less effective than ICS in preschoolers with asthma or recurrent wheezing.[12] If montelukast is considered for therapy, parents should be counseled that the FDA has required a boxed warning of the risk of serious mental health side effects; a decision to use montelukast should be based on shared decision making between the provider and caregiver.

Older Adults

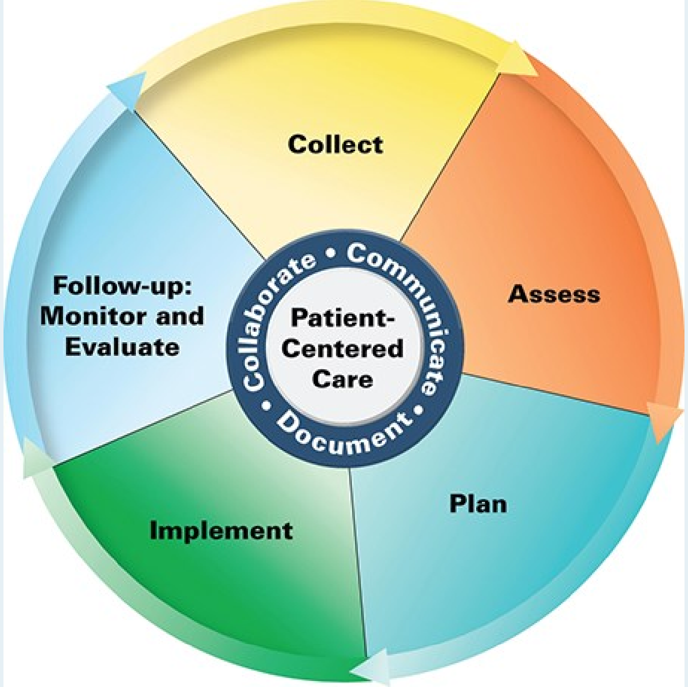
Older adults are at the highest risk of dying from asthma due to multiple contributing factors.[4] As in very young children, there have been few prospective studies evaluating drug therapies. In addition, older adults have a high co-morbidity burden which may impact response to therapies differently than younger patients, and adherence to treatment can be more challenging when multiple medications for different diseases are prescribed. Control of co-morbid conditions (obesity, smoking, depression, and rhinosinusitis) may be required to improve treatment outcomes.[12] Arthritis, vision impairment, and muscle weakness which may affect the inspiratory flow should be considered when selecting inhaler devices.[12] In addition, older adults may have difficulty distinguishing breathlessness due to aging or cardiovascular disease from symptoms of asthma.[12] Given their increased risk of osteoporosis and cataracts, older adults who require high doses of ICSs should have routine height measurements, bone mineral density determinations, and ophthalmic examinations.[12] Appropriate therapies for the prevention of osteoporosis should be instituted.[12] ICS use may contribute to skin bruising in older adults.

Pregnant Women

Asthma control may change during pregnancy; either improving or worsening and control may vary during each trimester.[12] Maternal asthma increases the risk of perinatal mortality, preeclampsia, preterm birth, and low-birth-weight infants.[12] More severe asthma is associated with increased risks, whereas better-controlled asthma is associated with decreased risks. The advantages of actively treating asthma during pregnancy far outweigh any risks of using ICS or albuterol and these medications are not associated with fetal abnormalities.[12] The safety of the newer biological treatments in pregnancy is unknown. Proper monitoring and control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to the mother or her fetus. Patients should be monitored monthly to assess asthma control. ICS should not be discontinued in women planning a pregnancy or who are pregnant.[12]

Pregnant women are particularly susceptible to viral infections leading to exacerbations and worsening asthma symptoms. These asthma exacerbations should be aggressively treated to avoid fetal hypoxia.[12] Moderate-to-severe exacerbations should be treated with SABA, oxygen, and early administration of systemic corticosteroids.[12] Hyperventilation during labor may induce bronchoconstriction and should be treated with SABA.[31]

Patient Care Process for the Management of Acute Asthma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Initial assessments
  - **A**irway, **B**reathing, **C**irculation
  - If signs of extreme distress, drowsiness, confusion, silent chest → start SABA, oxygen, consult ICU, consider intubation
- Patient characteristics (eg, age, race/ethnicity, sex, pregnancy status)
- Patient history (eg, past medical, known triggers, psychosocial history)
- Past exacerbation history (eg, past need for hospitalization, intensive care, or intubation) History of food allergy
- Current medications and prior response to controller therapies (eg, ICS+/−LABA; montelukast; LAMA; biologic therapies)

Assess

- Degree of severity of exacerbation—MILD or MODERATE (see Fig. 44-8) Can talk in phrases or sentences
  - Can sit up
  - Not agitated
  - Respiratory rate elevation mild to moderate
  - No sign of accessory muscle use
  - Oxygen saturation 90% to 95% (0.90-0.95)
  - PEF rate>50% of predicted (or previous best)
- Degree of severity of exacerbation—SEVERE (see Fig. 44-8)
  - Can only talk in single words

  - Hunched forward Agitated
  - Respiratory rate elevation severe (>30/min for adults)
  - Accessory muscle use evidence
  - Oxygen saturation <90% (0.90)
  - PEF rate ≤50% of predicted (or previous best)

Plan and Implement

- If MILD-MODERATE (see Fig. 44-8)
  - Start SABA
  - Consider ipratropium bromide
  - Titrate oxygen to keep 94% (0.94) or higher
  - Oral corticosteroids
- If SEVERE, use a team-based approach to immediately and simultaneously start SABA, oxygen, ICU involvement, and preparation for possible intubation (see Fig. 44-8)
  - Start SABA and ipratropium bromide
  - Titrate oxygen to keep 94% (0.94) or higher; use continuous oximetry and cardiac monitoring
  - IV corticosteroids (consider IV magnesium and high-dose ICS)

Follow-up: Monitor and Evaluate (see Fig. 44-8)

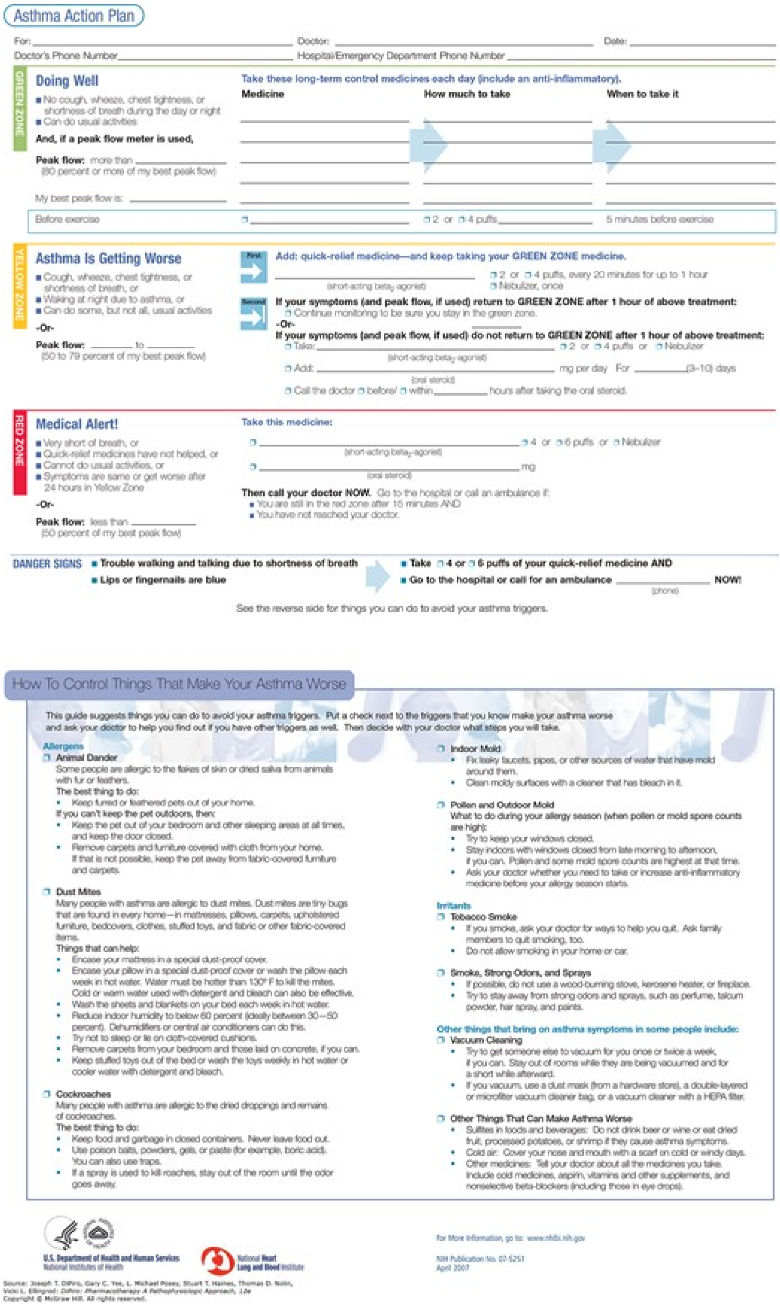
- Assess symptoms frequently
- If continuing deterioration, consider intubation and ICU transfer
- Measure lung function in all patients 1 hour after initial treatment if able
- Disposition
  - If continued signs/symptoms of distress and FEV_1 or PEF minimally improved, <60% predicted or personal best → continue treatment as above and reassess frequently
  - If significantly improved clinical signs/symptoms and FEV_1 or PEF improved to 60% to 80% predicted or personal best → consider for discharge planning

General Approach to the Management of Acute Severe Asthma

The primary goal in the treatment of acute severe asthma is to prevent death by recognizing the signs of deterioration and providing rapid treatment. Initial assessment includes history, physical examination, and objective assessments. It is important that therapy not be delayed, so the history and physical examination should be obtained while therapy is being initiated. The brief history will assess for onset and causes of the exacerbation; severity of symptoms and if associated with anaphylaxis; medication use, adherence, and response to current therapy; and risk factors for asthma-related death. Guidance for the self-management of acute asthma exacerbation should be provided to patients and caregivers using a written asthma action plan (Fig. 44-6).[43] This tool provides an individualized plan of action for patients based on symptoms and peak flow measurements. The action to be taken is based on whether the patient is in the green ("doing well"), yellow ("getting worse"), or red ("medical alert") zone.[43] For patients in the yellow or red zones, instructions for rescue treatment, including the dose and frequency, are provided. Most importantly, the asthma action plan should clearly state when to seek emergency care. The asthma-related risk factors for death include a history of near-fatal asthma requiring intubation and mechanical ventilation; hospitalization or emergency care in the past year; current or recent use of oral corticosteroids; no current use of ICSs; poor medication adherence; overuse of SABA therapy (more than one canister per month); history of psychiatric disease or psychosocial problems; lack of a written asthma action plan; food allergy in a patient with asthma; and co-morbidities such as pneumonia, diabetes, arrhythmias.[12]

FIGURE 44-6

Asthma Action Plan. (Reprinted from *National Heart, Lung, and Blood Institute. Digital Toolkit: Asthma Action Plan [updated December 2000].*)



Asthma Action Plan

For: ____ Doctor: ____ Date: ____
Doctor's Phone Number ____ Hospital/Emergency Department Phone Number ____

GREEN ZONE

Doing Well
- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flow meter is used,

Peak flow: more than ____
(80 percent or more of my best peak flow)

My best peak flow is: ____

Take these long-term control medicines each day (include an anti-inflammatory).

Medicine	How much to take	When to take it
Before exercise ☐ ____	☐ 2 or ☐ 4 puffs ____	5 minutes before exercise

YELLOW ZONE

Asthma Is Getting Worse
- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night due to asthma, or
- Can do some, but not all, usual activities

-Or-

Peak flow: ____ to ____
(50 to 79 percent of my best peak flow)

First **Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.**
____ (short-acting beta$_2$-agonist) ☐ 2 or ☐ 4 puffs, every 20 minutes for up to 1 hour
☐ Nebulizer, once

Second **If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:**
☐ Continue monitoring to be sure you stay in the green zone.
-Or-
If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:
☐ Take: ____ (short-acting beta$_2$-agonist) ☐ 2 or ☐ 4 puffs or ☐ Nebulizer
☐ Add: ____ (oral steroid) mg per day For ____ (3-10) days
☐ Call the doctor ☐ before/ ☐ within ____ hours after taking the oral steroid.

RED ZONE

Medical Alert!
- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-

Peak flow: less than ____
(50 percent of my best peak flow)

Take this medicine:
☐ ____ (short-acting beta$_2$-agonist) ☐ 4 or ☐ 6 puffs or ☐ Nebulizer
☐ ____ (oral steroid) mg

Then call your doctor NOW. Go to the hospital or call an ambulance if:
- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS
- **Trouble walking and talking due to shortness of breath**
- **Lips or fingernails are blue**

- **Take ☐ 4 or ☐ 6 puffs of your quick-relief medicine AND**
- **Go to the hospital or call for an ambulance ____ (phone) NOW!**

See the reverse side for things you can do to avoid your asthma triggers.

How To Control Things That Make Your Asthma Worse

This guide suggests things you can do to avoid your asthma triggers. Put a check next to the triggers that you know make your asthma worse and ask your doctor to help you find out if you have other triggers as well. Then decide with your doctor what steps you will take.

Allergens

☐ Animal Dander
Some people are allergic to the flakes of skin or dried saliva from animals with fur or feathers.
The best thing to do:
- Keep furred or feathered pets out of your home.

If you can't keep the pet outdoors, then:
- Keep the pet out of your bedroom and other sleeping areas at all times, and keep the door closed.
- Remove carpets and furniture covered with cloth from your home. If that is not possible, keep the pet away from fabric-covered furniture and carpets.

☐ Dust Mites
Many people with asthma are allergic to dust mites. Dust mites are tiny bugs that are found in every home—in mattresses, pillows, carpets, upholstered furniture, bedcovers, clothes, stuffed toys, and fabric or other fabric-covered items.
Things that can help:
- Encase your mattress in a special dust-proof cover.
- Encase your pillow in a special dust-proof cover or wash the pillow each week in hot water. Water must be hotter than 130° F to kill the mites. Cold or warm water used with detergent and bleach can also be effective.
- Wash the sheets and blankets on your bed each week in hot water.
- Reduce indoor humidity to below 60 percent (ideally between 30—50 percent). Dehumidifiers or central air conditioners can do this.
- Try not to sleep or lie on cloth-covered cushions.
- Remove carpets from your bedroom and those laid on concrete, if you can.
- Keep stuffed toys out of the bed or wash the toys weekly in hot water or cooler water with detergent and bleach.

☐ Cockroaches
Many people with asthma are allergic to the dried droppings and remains of cockroaches.
The best thing to do:
- Keep food and garbage in closed containers. Never leave food out.
- Use poison baits, powders, gels, or paste (for example, boric acid). You can also use traps.
- If a spray is used to kill roaches, stay out of the room until the odor goes away.

☐ Indoor Mold
- Fix leaky faucets, pipes, or other sources of water that have mold around them.
- Clean moldy surfaces with a cleaner that has bleach in it.

☐ Pollen and Outdoor Mold
What to do during your allergy season (when pollen or mold spore counts are high):
- Try to keep your windows closed.
- Stay indoors with windows closed from late morning to afternoon, if you can. Pollen and some mold spore counts are highest at that time.
- Ask your doctor whether you need to take or increase anti-inflammatory medicine before your allergy season starts.

Irritants

☐ Tobacco Smoke
- If you smoke, ask your doctor for ways to help you quit. Ask family members to quit smoking, too.
- Do not allow smoking in your home or car.

☐ Smoke, Strong Odors, and Sprays
- If possible, do not use a wood-burning stove, kerosene heater, or fireplace.
- Try to stay away from strong odors and sprays, such as perfume, talcum powder, hair spray, and paints.

Other things that bring on asthma symptoms in some people include:

☐ Vacuum Cleaning
- Try to get someone else to vacuum for you once or twice a week, if you can. Stay out of rooms while they are being vacuumed and for a short while afterward.
- If you vacuum, use a dust mask (from a hardware store), a double-layered or microfilter vacuum cleaner bag, or a vacuum cleaner with a HEPA filter.

☐ Other Things That Can Make Asthma Worse
- Sulfites in foods and beverages: Do not drink beer or wine or eat dried fruit, processed potatoes, or shrimp if they cause asthma symptoms.
- Cold air: Cover your nose and mouth with a scarf on cold or windy days.
- Other medicines: Tell your doctor about all the medicines you take. Include cold medicines, aspirin, vitamins and other supplements, and nonselective beta-blockers (including those in eye drops).

The physical examination should include the measurement of vital signs and the history to pay careful attention to complicating factors such as anaphylaxis and comorbid conditions that could be causing acute shortness of breath such as an inhaled foreign body, congestive heart failure, pulmonary infection, and pulmonary embolism.[12]

Objective assessments are keys to monitoring response to therapy and should be made before initiation of oxygen or drug treatment. Lung function testing by PEF or FEV_1 should be measured before treatment if possible and thereafter at 1 hour after starting treatment and then periodically until a response is achieved or no further improvement is evident.[12] Oxygen saturation is also monitored closely preferably by pulse oximetry and is a key parameter in young children who may not be able to perform lung function. Arterial blood gases are typically reserved for patients who are poorly responsive to initial treatment or deteriorating. A chest x-ray is rarely indicated unless there are physical signs of other or additional complicating features such as foreign body aspiration.

Oxygen therapy is initiated to achieve an arterial oxygen saturation of 93% to 95% in adolescents and adults and 94% to 98% in school-aged children and pregnant women or those with cardiac disease.[12] Oxygen therapy is continued until the patient has stabilized with continued use of pulse oximetry to monitor further oxygen need and response to medications.

The primary therapy of acute exacerbations is pharmacologic, which includes SABA and, depending on the severity, systemic corticosteroids, inhaled ipratropium, intravenous magnesium sulfate, and O_2. Treatments are typically administered concurrently to facilitate rapid improvement.

Serum electrolytes should be monitored in patients who take diuretics regularly and in patients with coexistent cardiovascular disease, as SABA can produce transient decreases in potassium, magnesium, and phosphate. The combination of high-dose β_2-agonists and systemic corticosteroids occasionally may result in excessive elevations of glucose and lactic acid.

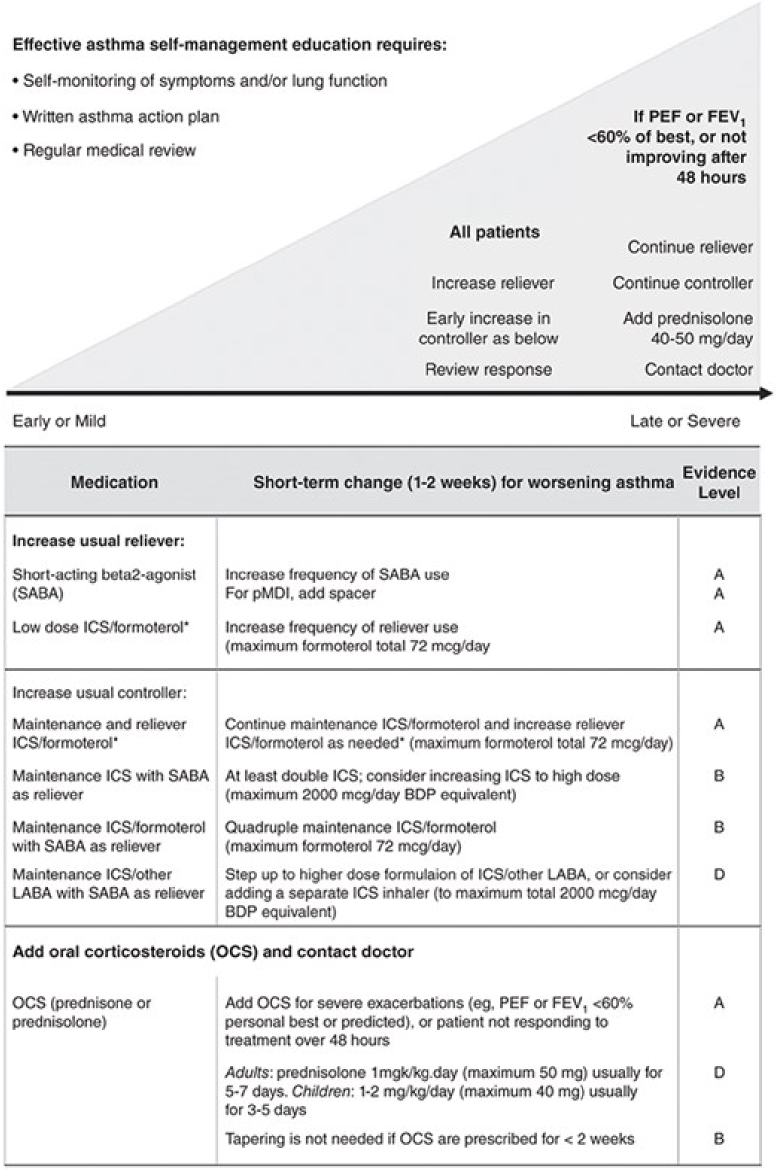
The initial response is measured 1 hour after the first three inhaled bronchodilator treatments are administered and provide the best indicator for the need for hospitalization.[12] Indicators for hospitalization typically rely on the degree of respiratory distress, oxygen requirement, and frequency of need for inhaled β_2-agonists. Adjunctive indicators may include an initial FEV_1 less than 25% predicted or PEF that is less than 40% of their personal best, and post-treatment FEV_1 or PEF that is 40% to 60%.[12] Other indicators of severe asthma include monosyllabic speech, inaudible breath sounds, sitting hunched forward, and use of accessory muscles. Patients with lung function that is 40% to 60% predicted may be considered for discharge after assessment of risk factors for death from asthma and the likelihood for follow-up care. Those with higher lung function can be discharged after risk factor and follow-up care assessment.[12]

Discharge planning after an ED visit or hospitalization includes arranging follow-up care within 1 week as well as reviewing strategies to improve asthma management. Referral to a specialist is suggested for those who have been hospitalized or frequently seek care in the ED despite having regular primary care. Strategies for preventing future urgent care visits include ensuring the patient understands the cause of the exacerbation, how to modify risk factors, how to correctly use medications and for what purpose, and having a written asthma action plan that includes self-assessment of worsening symptoms and home PEF values.[12]

Figures 44-7 and 44-8 illustrate the recommended therapies for the treatment of acute asthma exacerbations in-home and ED/hospital settings.[12] Note that Fig. 44-7 is from the GINA guidelines and includes a recommendation to increase the frequency of ICS-formoterol which is not yet standard practice in the United States and is Evidence Grade A. The dosages of the drugs for acute severe exacerbations are provided in Table 44-3.[3,12]

FIGURE 44-7

Self-management of worsening asthma in adults and adolescents with a written asthma action plan. *(© 2022 Global Initiative for Asthma, used with express permission, www.ginasthma.org.)*



Effective asthma self-management education requires:
• Self-monitoring of symptoms and/or lung function
• Written asthma action plan
• Regular medical review
If PEF or FEV1 <60% of best, or not improving after 48 hours
All patients
Increase reliever
Early increase in controller as below
Review response
Continue reliever
Continue controller
Add prednisolone 40-50 mg/day
Contact doctor
Early or Mild
Late or Severe

Medication	Short-term change (1-2 weeks) for worsening asthma	Evidence Level
Increase usual reliever:		
Short-acting beta2-agonist (SABA)	Increase frequency of SABA use For pMDI, add spacer	A A
Low dose ICS/formoterol*	Increase frequency of reliever use (maximum formoterol total 72 mcg/day	A
Increase usual controller:		
Maintenance and reliever ICS/formoterol*	Continue maintenance ICS/formoterol and increase reliever ICS/formoterol as needed* (maximum formoterol total 72 mcg/day)	A
Maintenance ICS with SABA as reliever	At least double ICS; consider increasing ICS to high dose (maximum 2000 mcg/day BDP equivalent)	B
Maintenance ICS/formoterol with SABA as reliever	Quadruple maintenance ICS/formoterol (maximum formoterol 72 mcg/day)	B
Maintenance ICS/other LABA with SABA as reliever	Step up to higher dose formulaion of ICS/other LABA, or consider adding a separate ICS inhaler (to maximum total 2000 mcg/day BDP equivalent)	D
Add oral corticosteroids (OCS) and contact doctor		
OCS (prednisone or prednisolone)	Add OCS for severe exacerbations (eg, PEF or FEV$_1$ <60% personal best or predicted), or patient not responding to treatment over 48 hours	A
	Adults: prednisolone 1mgk/kg.day (maximum 50 mg) usually for 5-7 days. *Children*: 1-2 mg/kg/day (maximum 40 mg) usually for 3-5 days	D
	Tapering is not needed if OCS are prescribed for < 2 weeks	B

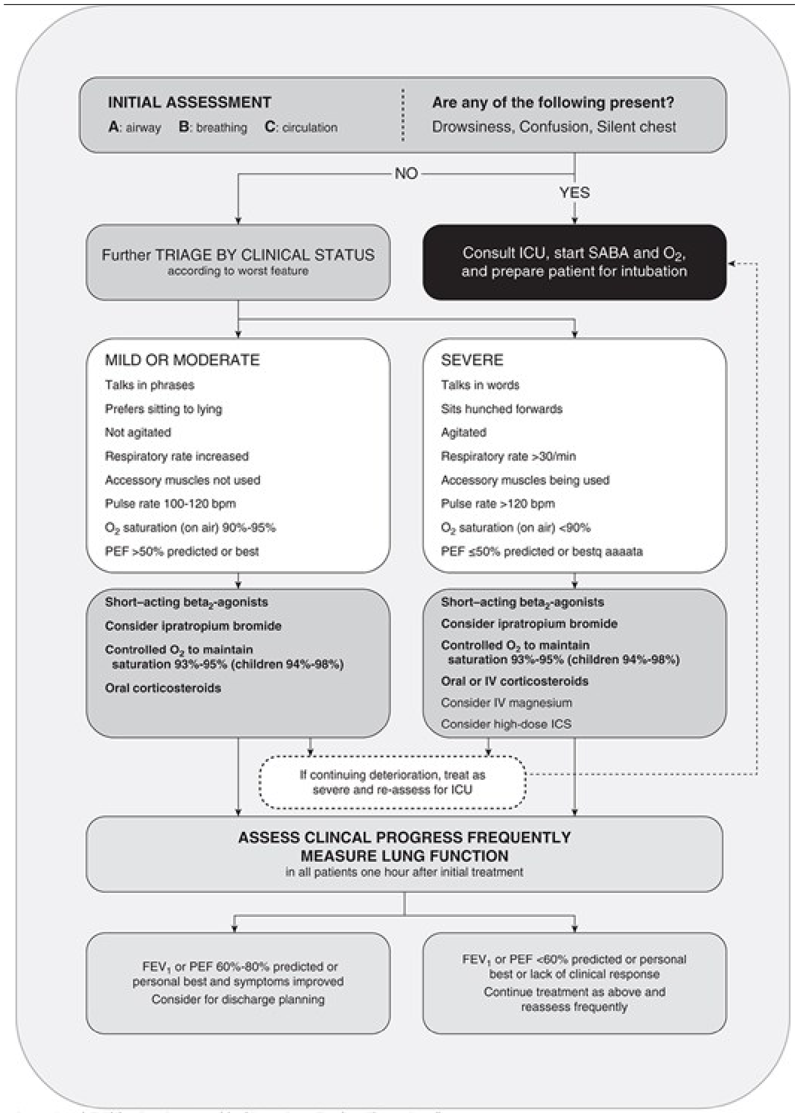
Management of asthma exacerbations in an acute care facility, for example, the emergency department. To obtain O$_2$ saturation in SI units (fraction) multiply the results expressed as a percentage by 0.01. *(© 2022 Global Initiative for Asthma, used with express permission, www.ginasthma.org.)*



INITIAL ASSESSMENT
A: airway B: breathing C: circulation
Are any of the following present?
Drowsiness, Confusion, Silent chest
NO
YES
Further TRIAGE BY CLINICAL STATUS
according to worst feature
Consult ICU, start SABA and O2, and prepare patient for intubation
MILD OR MODERATE
Talks in phrases
Prefers sitting to lying
Not agitated
Respiratory rate increased
Accessory muscles not used
Pulse rate 100-120 bpm
O2 saturation (on air) 90%-95%
PEF >50% predicted or best
SEVERE
Talks in words
Sits hunched forwards
Agitated
Respiratory rate >30/min
Accessory muscles being used
Pulse rate >120 bpm
O2 saturation (on air) <90%
PEF ≤50% predicted or bestq aaaata
Short-acting beta2-agonists
Consider ipratropium bromide
Controlled O2 to maintain saturation 93%-95% (children 94%-98%)
Oral corticosteroids
Short-acting beta2-agonists
Consider ipratropium bromide
Controlled O2 to maintain saturation 93%-95% (children 94%-98%)
Oral or IV corticosteroids
Consider IV magnesium
Consider high-dose ICS
If continuing deterioration, treat as severe and re-assess for ICU
ASSESS CLINICAL PROGRESS FREQUENTLY
MEASURE LUNG FUNCTION
in all patients one hour after initial treatment
FEV1 or PEF 60%-80% predicted or personal best and symptoms improved
Consider for discharge planning
FEV1 or PEF <60% predicted or personal best or lack of clinical response
Continue treatment as above and reassess frequently

TABLE 44-3

Dosages of Drugs for Treatment of Acute Severe Exacerbations of Asthma

	Dosages		
Medications	**≥12 Years Old**	**<12 Years Old**	**Comments**
Inhaled β-Agonists			
Albuterol nebulizer solution (5 mg/mL, 0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL)	2.5-5 mg every 20 minutes for three doses, and then 2.5-10 mg every 1-4 hours as needed, or 10-15 mg/hr continuously if in the emergency department or hospitalized	0.15 mg/kg (minimum dose 2.5 mg) every 20 minutes for three doses, and then 0.15-0.3 mg/kg up to 10 mg every 1-4 hours as needed, or 0.5 mg/kg/hr by continuous nebulization if in the emergency department or hospitalized	Only selective β_2-agonists are recommended. For optimal delivery, dilute aerosols to a minimum of 4 mL at gas flow of 6-8 L/min. Use face mask if <4 years
Albuterol MDI (90 µg/puff)	4-8 puffs every 30 minutes up to 4 hours, and then every 1-4 hours as needed	4-8 puffs every 20 minutes for three doses, and then every 1-4 hours as needed	In patients in severe distress, nebulization is preferred; use a VHC-type spacer with face mask if < 4 years old
Levalbuterol nebulizer solution (0.31 mg/3 mL, 0.63 mg/3 mL, 2.5 mg/1 mL, 1.25 mg/3 mL)	Give one-half the milligram dose of albuterol above	Give one-half the milligram dose of albuterol above	The single isomer of albuterol is twice as potent on a milligram basis Not recommended
Levalbuterol MDI (45 µg/puff)	See albuterol MDI dose above	See albuterol MDI dose above	See albuterol MDI dose one-half as potent as albuterol on a microgram basis Not recommended
Anticholinergics			
Ipratropium bromide nebulizer solution (0.25 mg/mL)	500 µg every 30 minutes for three doses, and then every 2-4 hours as needed	250 µg every 20 minutes for three doses, and then 250 µg every 2-4 hours	May mix in the same nebulizer with albuterol; only add to β_2-agonist therapy
Ipratropium bromide MDI (18 µg/puff)	8 puffs every 20 minutes as needed for up to 3 hours	4-8 puffs as needed every 2-4 hours	Not to be continued once hospitalized
Corticosteroids[a]			
Prednisone, methylprednisolone, prednisolone	50 mg in one or two divided doses (prednisone equivalent)	1 mg/kg (maximum 40 mg/day) in two divided doses (prednisone equivalent)	For outpatient "burst" use 1-2 mg/kg/day, maximum 60 mg, for 3-5 days in children and 40-60 mg/day in one or two divided doses for 5-7 days in adults

[a]No advantage has been found for very-high-dose corticosteroids in acute severe asthma, nor is there any advantage for IV administration over oral therapy. The usual regimen is to continue the oral corticosteroid for the duration of hospitalization. The final duration of corticosteroid therapy for an acute exacerbation may be from 3 to 10 days. If patients are then started on ICSs, there is no need to taper the systemic corticosteroid dose. ICSs can be started at any time during the exacerbation.

Data from Reference 3.

Special Populations

Infants and Children Under 5 Years Old

Infants and children younger than 5 years of age may be at greater risk of respiratory failure than older children and adults. Although treated with the same drugs, these younger children require the use of a pressurized MDI with a spacer or face mask as opposed to a mouthpiece for delivery of aerosolized medication. The face mask should be sized appropriately and should fit snugly over the nose and mouth. The pressurized MDI with spacer is preferred over a nebulizer because of its greater effectiveness and nebulizers can spread infectious particles.[12]

Children with severe exacerbations present with oxygen saturation of 92% (0.92) or less, speak in monosyllabic words, and have increased heart rate (above 180 beats/min if 0-3 years or above 150 beats/min if 4-5 years), central cyanosis, and inaudible breath sounds which indicate minimal ventilation sufficient to cause wheezing.[12] Hypoxemia is treated with oxygen to achieve oxygen saturation of 94% to 98% (0.94-0.98). Avoidance of hypoxemia is critical and treatment should be initiated with nebulized β_2-agonists delivered by an oxygen-driven nebulizer. Treatment should begin immediately even if a full assessment has not been taken. Initial SABA treatment is two puffs of albuterol, or if the exacerbation is severe, six inhalations of albuterol with a spacer/facemask. Treatment with 2 to 6 puffs of albuterol (severity dependent) may be repeated every 20 minutes for three doses with reassessment at the end of this treatment. Subsequent doses by nebulizer or two to three inhalations by spacer/facemask can be given every hour, but if symptoms do not resolve after 10 inhalations administered over 3 to 4 hours then a hospital admission is advised.[12] For nebulizer therapy, a dose of 2.5 mg albuterol every 20 minutes for 1 hour is administered and appropriate infection control measures must be followed.[12] Ipratropium bromide 1 to 2 puffs by pressurized MDI and spacer or nebulizer (250 µg) can be administered concurrently with albuterol during the first hour only.[12] Oral corticosteroids are administered at the time of inhaled β_2-agonists or intravenously in children unable to swallow. Nebulized magnesium sulfate may be administered as three doses in the first hour in children aged 2 years and older with severe exacerbations.[12] As in older children and adults, young children should be discharged with a prescription for oral corticosteroids for a 3- to 5-day treatment course and followed up within 7 days by a primary care provider.

Nonpharmacologic Therapy

Chronic Asthma

Although the mainstay of the management of asthma is pharmacologic therapy, it is likely to fail without concurrent attention to relevant environmental control and management of comorbidities that may contribute to respiratory symptoms and poor quality of life. Nonpharmacologic therapies are incorporated into GINA's recommendations for initiation of regular daily controller treatment, as well as the stepwise approach for adjusting treatment in adults, adolescents, and children.[11,12] The guidelines were designed to give healthcare providers a framework with which to develop the proper approach to the individualized therapy of patients. The heterogeneity of asthma demands an individualized approach to therapy with the basic goals of therapy as primary outcome measures.[11,12] The focus of controller therapy is the reduction of airway inflammation, control of symptoms, and reduction of future risks. Thus, current therapeutic options in asthma consist of acute reliever (rescue) medications for as-needed relief of breakthrough symptoms and exacerbations, and long-term control medications used for the prevention of symptoms and exacerbations and the suppression of inflammation and reduction of BHR.[11,12] Guidelines emphasize the importance of concurrently identifying and treating modifiable risk factors, such as active smoking and exposure to tobacco smoke, obesity, major psychological problems, major socioeconomic problems, confirmed food allergy, and allergen exposure if sensitized.[11,12] Occupational exposures, indoor allergens, and medications that may make asthma worse and should be evaluated when relevant.

In patients with known allergic triggers for their asthma, allergen avoidance has resulted in an improvement in symptoms, a reduction in medication use, and a decrease in BHR.[11] A multicomponent approach to environmental control is recommended in the 2020 Asthma Focused Updates because single-component interventions often are ineffective at improving asthma control.[11] Interventions should be tailored for individuals who have symptoms and/or positive allergy tests and who are exposed to specific allergens.[11] The 2020 Asthma Focused Updates provide a comprehensive evaluation of allergen mitigation strategies.[11] Some long-standing practices such as the use of acaricides to remove dust mites, carpet removal, use of air filtration systems, and purifiers are not effective even when included in a multi-component strategy.[11] However, if a home has pests (eg, cockroaches and mice) or a mold problem, a single component strategy to address the problem is warranted.[11] The use of HEPA vacuum cleaners, particularly for children, and impermeable pillow and mattress covers are recommended as part of a multicomponent strategy.[11]

Allergen-specific immunotherapy as either subcutaneous injections or sublingual administration is discussed in the section "General Approach to the Management of Chronic Asthma". Allergen treatment should be directed to specific allergens to which the patient has documented sensitivity. The 2020 Asthma Focused Updates only recommends subcutaneous therapy for asthma management which may improve symptom scores and reduce medication use in patients with documented allergen sensitivity.[11] In addition, it may have a disease-modifying effect and reduce clinical asthma severity over time.[11] The efficacy of multiple-allergen (vs single-allergen) subcutaneous immunotherapy is an area identified for future study.[11] The burden of frequent healthcare visits for immunotherapy administration must be considered before starting therapy as treatment will need to be continued for several years before there is sustained improvement in symptoms.

Acute Asthma

Infants and young children may be mildly dehydrated owing to increased insensible loss, vomiting, and decreased intake.[44] Unless dehydration has occurred, increased fluid therapy is not indicated in acute asthma management because the capillary leak from cytokines and increased negative intrathoracic pressures may promote edema in the airways.[44] Correction of significant dehydration is always indicated, and the physical examination and urine specific gravity may help to guide therapy in young children, in whom the state of hydration may be difficult to determine.

Oxygen therapy is the primary nonpharmacologic therapy for the management of acute asthma and is discussed in the section "General Approach to the Management of Acute Severe Asthma". Sedatives should not be given because anxiety may be a sign of hypoxemia, which could be worsened by central nervous system depressants.[44] Antibiotics are also not indicated routinely because viral respiratory tract infections are the primary cause of asthma exacerbations.[44] Antibiotics should be reserved for patients who have signs and symptoms of pneumonia (eg, fever, pulmonary consolidation, and purulent sputum from polymorphonuclear leukocytes).

Respiratory failure or impending respiratory failure as measured by rising $PaCO_2$ (greater than or equal to 45 mm Hg [6 kPa]) or failure to correct hypoxemia with supplemental O_2 therapy is treated first with noninvasive ventilation and eventually with intubation and mechanical ventilation if needed. Oral intubation facilitates secretion removal and bronchoscopy and decreases airway resistance.[45] Heavy sedation and neuromuscular blockade may be needed to reduce ventilatory dyssynchrony in order to improve lung volume and respiratory rate.[45] Oxygen consumption, CO_2 production, and lactate accumulation may be mitigated by using neuromuscular blockade in mechanically ventilated patients.[45]

Patient Education

⑦ The development of a patient–healthcare provider partnership in care through patient education and the teaching of patient self-management skills should be the cornerstone of any treatment program.[12] There are a number of published self-management programs for children and adults available through the American Lung Association, Asthma and Allergy Foundation of America, asthma treatment centers, and the guidelines from NAEPP and GINA. Asthma self-management programs have been shown to improve patient adherence to medication regimens, self-management skills, and use of healthcare services.[12]

Self-management programs instruct patients in the pathogenesis of asthma and the appropriate use of their medications (including the rationale for treatment and why controllers and relievers are needed), teach patients to recognize triggers for their asthma and early signs of deterioration, how to keep track of symptoms (with or without a diary), and take action.[12] Short-term home PEF monitoring can be used following an exacerbation to assess response to treatment, determine if symptoms seem excessive, assess a baseline for asthma action plans, or evaluate triggers (such as occupational triggers) and is typically recorded for a few weeks.[12] Longer-term PEF monitoring is generally only recommended for those patients with a history of sudden severe asthma exacerbations, difficult-to-control severe asthma, or poor symptom perception.[12]

The NAEPP has recommended a PEF monitoring system or symptom-based action plan using a traffic light scenario (based on a percentage of normal predicted values or personal best values): the green zone is equal to 80% to 100%, the yellow zone is equal to 50% to 79%, and the red zone is less than 50%. The yellow zone is cautionary and requires increasing as-needed bronchodilator use and possibly beginning prednisone if not improved, whereas the red zone warrants contacting the patient's healthcare provider.[43] Samples of clinically tested written action plans that are PEF or symptom-based are available from NAEPP and other sources.[43]

Patient education is essential before monitoring can be effective. It is successful regardless of the healthcare provider who provides it. The NAEPP and GINA advocate significant involvement of all points of patient care in the educational process. The provision of written action plans enhances the success of education and is considered an essential component of care.

Pharmacologic Therapy

β_2-Agonists

⑤ ② The β_2-agonists are the most effective bronchodilators available. β_2-Agonists do not inhibit the late asthmatic response to allergen challenge or the subsequent BHR. Long-term administration of β_2-agonists does not reduce BHR, confirming a lack of significant anti-inflammatory activity. β_2-Adrenergic stimulation also activates Na^+-K^+-ATPase, produces gluconeogenesis, and enhances insulin secretion, resulting in a mild-to-moderate decrease in serum potassium concentration by driving potassium intracellularly. The chronotropic response to β_2-agonists is mediated in part by baroreceptor reflex mechanisms as a result of the drop in blood pressure from vascular smooth muscle relaxation, as well as by direct stimulation of cardiac β_2-receptors and some β_1 stimulation at high concentrations.

Table 44-4 compares the various short-, long-, and ultra-long-acting β-adrenergic agonists used in asthma in terms of onset and duration of action.[46] The β_2-agonists are functional or physiologic antagonists, in that they relax airway smooth muscle regardless of the mechanism for constriction. When administered in equipotent doses, all the short-acting drugs produce the same intensity of response; the only differences are in duration of action and cardiac toxicity.[46] All the β_2-agonists are more bronchoselective when administered by the aerosol route. Aerosol administration of a SABA provides more rapid response and greater protection against provocations that induce bronchospasm such as exercise and allergen challenges than does systemic administration.[46]

TABLE 44-4

Onset and Duration of Action of β-Adrenergic Agonists

	Onset and Duration of Action[a]		
Agent	Bronchodilation (hours)	Protection (hours)[a]	Onset of bronchodilation
SABA			
Albuterol/levalbuterol	4-8	2-4	1-2 minutes
Terbutaline	4-6	2-4	1-2 minutes
LABA			
Formoterol	≥12	≥12	1-2 minutes
Salmeterol	≥12	≥12	10 minutes
Ultra-LABA			
Indacaterol	≥24	≥24	1-2 minutes
Olodaterol	≥24	≥24	1-2 minutes
Vilanterol	≥24	≥24	1-2 minutes

[a] Protection refers to the prevention of bronchoconstriction induced by exercise or nonspecific bronchial challenges.

Both the intensity and duration of response to β_2-agonists are dose-dependent, and, more important, the dose-response relationship is dynamic. At increasing levels of baseline bronchoconstriction (irrespective of the stimulus), the dose-response curve is shifted to the right, and the duration of bronchodilation is decreased. This shift is reflected in the need for higher, more frequent doses in acute asthma exacerbations; the duration of protection against significant provocation is much less than the duration of bronchodilation in chronic stable asthma for short-acting inhaled β_2-agonists (see Table 44-4).[46]

Chronic administration of β_2-agonists leads to downregulation (decreased number of β_2-receptors) and a decreased binding affinity (desensitization) for these receptors.[46] Systemic corticosteroid therapy can both prevent and partially reverse this phenomenon. However, the use of ICSs has minimal ability to prevent tolerance to β_2-agonists.[46] Tolerance primarily reduces the duration of bronchodilation as opposed to diminishing the peak response, although the latter can occur as well. A significantly greater tolerance develops in other tissues (eg, lymphocytes and cardiac and skeletal muscle) compared with the lung, primarily as a result of the surplus β_2-receptors found in respiratory smooth muscle. Tolerance to the extra-pulmonary effects (cardiac stimulation and hypokalemia) may account for a lack of significant cardiac effects despite chronic inhaled β_2-agonist therapy. Thus, chronic β_2-agonist administration produces a tolerance that can be easily overcome by increasing the dose or by administering systemic corticosteroids. Most of the tolerance occurs within 1 to 2 weeks of regular administration and does not worsen with continued administration. As would be expected from a receptor phenomenon, cross-tolerance to all β_2-agonists develops.

Short-Acting β_2-Agonists

④ The short-acting inhaled β_2-agonists are the most effective bronchodilators and the treatment of first choice for the management of acute severe asthma.[12] In adults, administration as either continuous nebulization in a large volume nebulizer or intermittent administration (every 20 minutes for three doses) over 1-hour results in equivalent improvement.[12] Systematic reviews of continuous versus intermittent SABA in severe acute asthma have conflicting findings.[12] There is no role for intravenous β_2- agonists in patients with severe asthma (Evidence A).[12] Effective doses of aerosolized β_2-agonists can be delivered successfully through mechanical ventilator circuits to infants, children, and adults in respiratory failure secondary to severe airway obstruction.

The doses of inhaled β_2-agonists for acute severe asthma exacerbations (see Table 44-3) have been derived empirically. The β_2-agonists follow a log-linear dose-response curve. In addition, the dose-response curve is shifted to the right by more severe bronchospasm or by increased concentrations of bronchospastic mediators, which is characteristic of functional antagonists. The ability to increase the dose of SABA by as much as 5- to 10-fold over doses producing adequate bronchodilation in chronic stable asthma is what contributes to their efficacy in reversing the bronchospasm of acute severe exacerbations. The nebulizer dose of inhaled β_2-agonists for children often is listed on a weight basis (milligrams per kilogram). The preferred method from both an efficiency and economic perspective with a MDI and spacer.[12]

The inhaled β_2-agonists produce similar efficacy whether delivered by MDI plus valved holding chamber (VHC) or nebulization in treating acute severe exacerbations in the ED and hospital. The preferred choice is an MDI with a valved spacer, particularly considering the risk of spreading infectious viral particles via nebulization[12] Most DPIs are not used for acute severe asthma exacerbations due to the higher inspiratory flows required for adequate drug delivery.[12]

Unlike in children, nebulized albuterol is administered in adults in a fixed-dose (vs a weight-based dose) in order to avoid excessive cardiac stimulation.[3] Conversely, children younger than 5 years are dosed based on weight and should have a fixed minimal dose (2.5 mg albuterol or equivalent) due to the resultant underdosing when weight-based dosing is used; higher doses (up to 10 mg based on weight) can be administered every 1 to 4 hours as needed (Table 44-3). Initial doses of inhaled β_2-agonists can produce vasodilation, worsening ventilation-perfusion mismatch, slightly lowering O_2 saturation or Pa_{O_2}.[12] High doses of inhaled β_2-agonists can produce a decrease in serum potassium concentration, an increase in heart rate, and an increase in serum glucose and lactic acid concentration. Electrolyte monitoring may be needed in patients with preexisting heart disease who receive frequent doses for an acute exacerbation.[9] Both children and adults receiving continuously nebulized β_2-agonists (not a recommended treatment)[12] have demonstrated decreased heart rate as their lung function improves which indicates elevated heart rate is not an indication to use lower doses or to avoid using inhaled β_2-agonists.

β_2-Agonists can exist as racemic mixtures (eg, albuterol, salmeterol, formoterol) or as single enantiomers (eg, levalbuterol, indacaterol, olodaterol, vilanterol). There is no evidence to support the use of levalbuterol over albuterol for the treatment of acute severe exacerbations in either children or adults with respect to efficacy or adverse effects.[47]

Primatene Mist® MDI is the only inhaled asthma medication available without a prescription and was reintroduced onto the market in late 2018 as an MDI with a hydrofluoroalkane propellant. Primatene Mist® should only be used for the temporary relief of mild symptoms of intermittent asthma in patients 12 years and older. If improvement is not seen within 20 minutes or symptoms become worse, or the patient requires more than eight inhalations in a 24-hour period or has a recurrence of symptoms within a week, the patient should see a physician for additional evaluation and treatment. Primatene Mist® is less effective than prescription SABAs.

A SABA is also indicated for the as-needed treatment of intermittent episodes of bronchospasm. They inhibit EIB in a dose-dependent fashion and provide complete protection for a 2-hour period following inhalation with varying levels of patient-dependent protection over 4 hours.[12] Although the regular administration of β2-agonists slightly decreases the protective effect, two inhalations prior to exercise still essentially block EIB completely (1% vs 5% drop in FEV_1).[12] The GINA guidelines also recommend low-dose ICS-formoterol taken before exercise but this treatment is not recommended by NAEPP.[11,12]

Long-Acting and Ultra Long-Acting Inhaled β_2-Agonists

The two LABAs, formoterol and salmeterol, provide long-lasting bronchodilation (greater than or equal to 12 hours) and are dosed twice daily[48] (see Table 44-4). Formoterol, in combination with an ICS, may be dosed on a daily and as-needed basis (thus, more frequently than twice daily). Unlike the more water-soluble SABA, the long-acting agents are lipid-soluble, readily partitioning into the outer phospholipid layer of the cell membrane.[48] In addition, ultra-LABAs (indacaterol, vilanterol, and olodaterol) have a 24-hour bronchodilator duration of effect permitting once-daily dosing. Only vilanterol in combination with fluticasone furoate (with and without umeclidinium, an anticholinergic) is available for once-daily dosing for asthma in adults aged 18 years and older in the United States. Products containing indacaterol and olodaterol are only indicated for COPD but are being evaluated for asthma.

The LABAs and ultra-LABAs are more β_2-selective than albuterol and more bronchoselective by virtue of their property of remaining in the lung tissue cell membrane, which produces its longer duration.[48] The onset of action (time required to increase FEV_1 by 12% over baseline) is similar to that of albuterol for LABAs and ultra-LABAs with the exception of salmeterol which has an onset of approximately 10 minutes. LABAs are available as a single entity and as fixed-dose combinations with ICSs (see below) though single-entity LABA products are FDA approved for use only with ICS. Patients need to be counseled to continue to use their SABA for acute exacerbations while receiving the ICS/LABA combination products.

As with SABA, tolerance can occur with chronic administration of LABAs and seems to plateau after about 1 week of regular therapy but response recovers rapidly after only 2 to 3 days of non-use.[48] Long-term trials have shown no diminution in bronchodilator response but a partial loss of the bronchoprotective effect against methacholine, histamine, and exercise challenge.[48] These effects do not seem to have a significant impact on the quality of asthma control with chronic daily use.

Concern for risks with LABA use began shortly after approval of the first available LABA, salmeterol, with reports of respiratory deaths in salmeterol users, and risks were evaluated in multiple meta-analyses which resulted in Boxed Warnings on the labeling of products containing an ICS-LABA.[12] In response to these findings, the FDA mandated several large clinical trials by the manufacturers to evaluate the risk of ICS-LABA therapy on serious asthma-related adverse effects. The results of these trials which included over 41,000 patients aged 12 years and older, and a single trial in children 4 to 11 years old, indicate that there is no significantly increased risk of asthma-related hospitalizations, intubations, or asthma-related deaths with ICS-LABA compared to ICS; the FDA has removed the Boxed Warning for ICS-LABA products but has retained it for single-ingredient LABA products.[49]

Corticosteroids

④ Corticosteroids are the most effective anti-inflammatories available to treat asthma.[11,12] Actions useful in treating asthma include: (a) increasing the number of β_2-adrenergic receptors and improving the receptor responsiveness to β_2-adrenergic stimulation, (b) reducing mucus production and hypersecretion, (c) reducing BHR, and (d) reducing airway edema and exudation. The glucocorticoid receptor is found in the cytoplasm of most body cells, explaining the multiple effects of systemic corticosteroids. There is no difference between glucocorticoid receptors found throughout the body; however, genetic differences in the glucocorticoid receptor among individuals may explain some of the variations in response.[50] The corticosteroids are lipophilic, readily cross the cell membrane, and combine with the glucocorticoid receptor. The activated glucocorticoid receptor complex then enters the nucleus, where it acts as a transcription factor leading to gene activation or suppression.[50] This leads to specific mRNA production, resulting in increased production of anti-inflammatory mediators and suppression of genes regulating the expression of several pro-inflammatory cytokines such as tumor necrosis factor-α, GM-CSF, interferon-γ, IL-1, IL-4, IL-5, IL-6, IL-8, IL-10, and IL-13.[50] In addition, the activated glucocorticoid receptor complex can act directly with transcription factors, nuclear factor-κB, and activating protein 1 to prevent the action of pro-inflammatory cytokines on the cell.[50]

Given that glucocorticoids work by altering gene expression, the time required to see a particular effect depends on the time required for new protein synthesis, decreased formation of the particular mediator, and resolution of the inflammatory response. While the cellular and biochemical effects are immediate, variable amounts of time are required to produce a clinical response. β_2-Receptor density increases within hours of corticosteroid administration leading to improved responsiveness to β2-agonists. In acute severe asthma, 3 to 8 hours may be required before any clinical response is noted.[51] The chronic use of corticosteroids does not induce a state of corticosteroid dependence and there is no evidence of tolerance produced by chronic administration.

The systemic and inhaled corticosteroids most commonly used in the treatment of asthma are compared in Table 44-5.[51,52] The pharmacokinetic and pharmacodynamic parameters (receptor binding affinity, bioavailability, clearance) influence the therapeutic index of inhaled corticosteroids. Higher receptor binding affinities and longer half-lives contribute to both improved efficacy but also increase the potential for systemic adverse effects. These factors affect the relative efficacy between products and thus may influence treatment decisions.

TABLE 44-5

Pharmacodynamic/Pharmacokinetic Comparison of the Corticosteroids

Systemic	Anti-inflammatory Potency	Mineralocorticoid Potency	Duration of Biologic Activity (hours)
Hydrocortisone	1	1	8-12
Prednisone	4	0.8	12-36
Methylprednisolone	5	0.5	12-36
Dexamethasone	25	0	36-72
	Receptor Binding Affinity[a]	Oral Bioavailability (%)	Systemic Clearance (L/hr)
Beclomethasone dipropionate/monoproprionate[b]	0.4/13.5	20/40	150/120
Budesonide	9.4	11	84
Ciclesonide/des-ciclesonide[b]	0.12/12	<1/<1	152/228
Flunisolide	1.8	20	58
Fluticasone proprionate	18	≤1	66
Mometasone furoate[c]	23	<1	53

[a] Receptor binding affinities are relative to dexamethasone equal to 1.

[b] Beclomethasone diproprionate and Ciclesonide are prodrugs that are activated in the lung to their active metabolites beclomethasone monopropionate and des-ciclesonide, respectively.

[c] Mometasone furoate was studied in a different receptor system. Value estimated from relative values of beclomethasone dipropionate and fluticasone proprionate in that system.

Systemic Corticosteroids

Systemic corticosteroids are indicated in all patients with acute severe asthma exacerbations not responding completely to initial SABA administration (every 20 minutes for three doses) and should be administered within 1 hour of presentation to reduce the risk of hospitalization.[12] Clinical improvement is noted after approximately 4 hours.[12] IV therapy offers no therapeutic advantage over oral administration except in patients who are too dyspneic to swallow, vomiting, or intubated.[12] This therapy usually is continued until hospital discharge. There is no need to taper the systemic corticosteroid dose following discharge from the hospital in patients who are prescribed an ICS for outpatient therapy (Evidence B).[12] Adults are effectively treated with a 5- to 7-day course of therapy but children typically require only 3- to 5-days (Evidence A).[12] Very short courses (3-5 days) are effective in reducing hospitalization from acute exacerbations.[12] Use of the shorter-acting corticosteroids such as prednisone will produce less adrenal suppression than the longer-acting dexamethasone.[12] Dexamethasone for 1 or 2 days versus a 5-day course of prednisone/prednisolone may be an option for children and has the benefit of causing less vomiting.[12] If there is an inadequate response to dexamethasone, switching to prednisone should be considered.[12] Multiple daily dosing of systemic corticosteroids for the initial therapy of acute asthma exacerbations is warranted because receptor binding affinities of lung corticosteroid receptors are decreased in the face of airway inflammation. However, patients with less-severe exacerbations may be treated adequately with once-daily administration.[2]

The beneficial and adverse effects of corticosteroids in asthma are dose and duration-dependent. Adverse effects can occur in adults and children even after a short duration (<14 days) of therapy. In adults, there is an increased risk of 1.8- to 5.3-fold in fracture, gastrointestinal bleeding, sepsis, venous thromboembolism, and heart failure (the only adverse events evaluated) in the 30 days following a short course of systemic corticosteroids.[53,54] A similar pattern is observed in children with a 1.8- to 2.2-fold increased risk in gastrointestinal bleeding, sepsis, and pneumonia.[55] Adverse effects of chronic daily use of oral corticosteroids are well known (Table 44-6). The clinician must continually balance the toxicity of chronic systemic corticosteroid therapy with the control of asthma symptoms. The ideal use is to administer the systemic corticosteroids in a short "burst" (< 7 days) and then to maintain the patient on appropriate long-term control therapy with ICSs.[12]

TABLE 44-6

Adverse Effects of Chronic Systemic Glucocorticoid Administration

Hypothalamic-pituitary-adrenal suppression
Growth retardation
Skeletal muscle myopathy
Osteoporosis/fractures
Aseptic necrosis of bone
Pancreatitis
Pseudotumor cerebri
Psychiatric disturbances
Sodium and water retention
Hypokalemia/hyperglycemia
Hypertension
Skin striae
Impaired wound healing
Inhibition of leukocyte and monocyte function
Subcutaneous tissue atrophy
Glaucoma
Posterior subcapsular cataracts
Moon facies
Central redistribution of fat

Inhaled Corticosteroids

The principal advantage of the ICSs is their high topical potency to reduce inflammation in the lung and low systemic activity.[51] The ICSs have high receptor binding affinity which is related to potency, and ICS products differ from each other in binding affinity by as much as 10- to 100-fold.[51] However, potency differences can be overcome simply by giving different microgram dosages of the drug (Table 44-5). Depending upon the microgram per inhalation, the potency differences between products will be reflected by the number of inhalations required to achieve the same therapeutic effect. Products that require more inhalations per dose or that must be administered twice daily may result in poorer adherence.

In the low-to-medium doses recommended (Tables 44-7 and 44-8), ICSs are safe for long-term administration. They do not reduce airway remodeling or prevent the loss of lung function seen in some patients with persistent asthma.[56] ICS therapy does not prevent the development of asthma in high-risk infants or induce asthma remission as BHR and other measures of inflammation return to pretreatment levels soon after the discontinuation of therapy.[12] The sensitivity and consequent clinical response to ICSs can vary among patients.[11,12]

TABLE 44-7

Inhaled Corticosteroids and Comparative Daily Dosages in Adults and Adolescents (12 Years and Older)

	Comparative Daily Dosages (µg) of Inhaled Corticosteroids		
	Low Dose	**Medium Dose**	**High Dose**

[a] Dry powder inhaler.

[b] Hydrofluoroalkane.

[c] Metered-dose inhaler.

Aerosol delivery of the corticosteroid is variable and is influenced by the nominal dose from the specific device (eg, that dose that leaves the actuator) and any device attached to MDIs to improve inhalation technique. Different devices which contain the same chemical entity may result in twofold differences in delivery. Thus, the delivery method can make a significant difference in the relative dose or therapeutic index.[12]

All ICSs are approved for once- or twice-daily dosing. The ICSs have pharmacokinetic differences that result in different topical/systemic activity.[51] Most evidence is consistent with log-linear dose-response curves for both indirect (measures to assess efficacy such as lung function, BHR, symptom control) and direct responses (receptor activity). The log-linear nature of the dose-response curve for ICS clinical effects makes dose-response relationships for efficacy difficult to establish. Alternatively, comparative potency effects may be based upon the dose-response adverse effects on hypothalamic-pituitary-adrenal axis suppression.[51] Comparable ICS doses (see Tables 44-3 and 44-4) are based on extensive clinical trial data.[12] Clinically comparable doses take into consideration drug potency differences as well as device delivery differences but not the potential for systemic activity and potential adverse effects.

Because the glucocorticoid receptors within the various tissues are the same, differences in the pharmacokinetic profile are required to produce differences in the topical/systemic effect ratio (therapeutic index).[51] Pharmacokinetic properties that enhance topical selectivity include higher potency, rapid systemic clearance, poor oral bioavailability, and prolonged residence time in the lung.[51] Due to their high lipophilicity, systemic clearance of the available ICSs is very rapid, approaching the rate of liver blood flow with the exception of beclomethasone diproprionate and ciclesonide, which are prodrugs metabolized in the lung by esterases to the active compounds, beclomethasone monopropionate, and des-ciclesonide.[51] However, the ICSs differ markedly in their oral bioavailability, although they all undergo rather extensive first-pass metabolism to less active substances when absorbed.[51] The ICSs produce dose-dependent systemic effects, contributed by the orally absorbed fraction and the fraction absorbed from the lung. (Table 44-9). Essentially, all the drug that reaches the lung is absorbed systemically; thus, a slow absorption from the lung results in an apparent long elimination half-life and enhances topical selectivity by lowering the systemic concentration. The potential advantage of the drugs with low oral bioavailability is obviated by using an MDI plus spacer device for the drugs with higher oral bioavailability because appropriate spacers substantially reduce the oral amount delivered.[12] The use of VHCs also can increase systemic activity by increasing lung delivery of drugs that are not absorbed significantly orally.[51] Mouth rinsing and spitting will also reduce oral absorption and are particularly useful for DPI devices.[12]

TABLE 44-9

Effects of Inhaled Corticosteroids

Beneficial Effects	Potential Adverse Effects
• Decrease eosinophil numbers • Decrease mast cell numbers • Decrease T-lymphocyte cytokine production • Inhibit transcription of inflammatory genes in airway epithelium • Reduce endothelial cell leak • Upregulate β_2-receptor production • Reduce airway epithelial subbasement membrane thickening	• Hoarseness, dysphonia, thrush • Growth retardation, skeletal muscle myopathy • Osteoporosis, fractures, and aseptic necrosis of the hip • Posterior subcapsular cataract formation and glaucoma • Adrenal axis suppression, immunosuppression • Impaired wound healing, easy bruising, skin striae • Hyperglycemia/hypokalemia, hypertension • Psychiatric disturbances

The response to ICSs is somewhat delayed. Most patients' symptoms will improve in the first 1 to 2 weeks of therapy and will reach maximum improvement in 4 to 8 weeks.[3] Improvement in baseline FEV_1 and PEF may require 3 to 6 weeks for maximum improvement, whereas improvement in BHR requires 2 to 3 weeks and approaches maximum in 1 to 3 months but may continue to improve over 1 year.[2] Most of the improvement in these parameters occurs at low-to-medium doses, and there is a large variability in response, with 10% of patients not demonstrating an improvement in either parameter.

Local adverse effects from ICSs include oropharyngeal candidiasis and dysphonia that are dose-dependent. The dysphonia (reported in 5%-20% of patients) is due to a local corticosteroid-induced myopathy of the vocal cords. The use of a spacer device with MDIs can decrease oropharyngeal deposition and thus decrease the incidence and severity of local side effects.[12] In infants who require ICS delivery through a face mask, the parent should clean the nasal-perioral area with a damp cloth following each treatment to prevent oropharyngeal candidiasis.

Systemic adverse effects can occur with any of the ICSs given in a sufficiently high dose.[12] Long-term adverse effects of greatest concern include growth suppression in children, osteoporosis, cataracts, dermal thinning, easy bruising, and adrenal insufficiency and crisis.[2] Growth retardation may occur with low-to-medium ICS doses. However, the growth reduction is transient, in that growth velocity is reduced in the first 6 months to 2 years of therapy and then returns to normal.[12] The effect is small (1-2 cm total) and not cumulative, but does persist into adulthood (difference of 0.7% from adult height).[12] The suppression of the HPA axis and decreased bone mineralization are dose-dependent and are not significant clinically except at high doses. The risks, therefore, depend on the therapeutic index of each ICS and its delivery device.

Many of the ICSs, including fluticasone propionate, budesonide, ciclesonide, and mometasone furoate, are metabolized in the GI tract and liver by cytochrome (CYP) 3A4 isoenzymes. Potent inhibitors of CYP3A4 such as ritonavir, itraconazole, and ketoconazole have the potential for increased systemic concentrations of these ICSs by increasing oral availability and decreasing systemic clearance.[12] Some cases of clinically significant Cushing's syndrome and secondary adrenal insufficiency have been reported.[12]

There is no specific pharmacologic or pharmacokinetic aspect of the current ICSs that allows for once-daily dosing because all the agents studied (both the older low-potency ICSs and newer high-potency ICSs) have been effective, provided that patients had relatively mild-to-moderate asthma. More severe patients may require multiple daily dosing. The inflammatory response of asthma has been shown to inhibit corticosteroid-receptor binding. Once asthma is controlled, many patients are able to reduce the ICS dose and maintain control.

Anticholinergics

Anticholinergic agents have a long history of use for asthma, with an evolving role in the chronic management of asthma.[58] Anticholinergics are competitive inhibitors of muscarinic receptors. Unlike β_2-agonists, they are not functional antagonists, rather they reverse cholinergic-mediated bronchoconstriction. This difference in mechanism supports the combined use of anticholinergics and β_2-agonists in the treatment of severe acute asthma exacerbations. The normal bronchial tone is maintained through parasympathetic innervation of the airways via the vagus nerve.[58] A number of the triggers and mediators of asthma (ie, histamine, prostaglandins, sulfur dioxide, exercise, and allergens) produce bronchoconstriction in part through vagal reflex mechanisms.[58] Studies consistently demonstrate that anticholinergics are effective bronchodilators in asthma. There is some evidence that anticholinergics may reduce allergen-induced and methacholine-induced airway responsiveness.[58]

Five muscarinic receptor subtypes (M_1 through M_5) have been identified; M_1, M_2, and M_3 are the principal receptors in the airway.[58] Available anticholinergics ipratropium, aclidinium (not indicated for asthma), glycopyrrolate (not indicated for asthma), and tiotropium are nonselective antagonists of M1, M2, and M3 receptors; umeclidinium bromide which is indicated for persistent asthma is selective for the M3 receptor. M1 receptors are found in epithelial cells and the ganglia and regulate electrolyte and water secretion; M2 receptors, on airway smooth muscle and parasympathetic neurons, have a limited role on smooth muscle constriction; M3 receptors are the primary subtype responsible for smooth muscle bronchoconstriction and mucus secretion.[58] Ipratropium bromide has a duration of action of 4 to 8 hours and is used for the relief of acute asthma symptoms in combination with SABA. The time to reach maximum bronchodilation for ipratropium is considerably slower than for aerosolized SABA (30-60 minutes vs 5-10 minutes). However, this difference is of little clinical consequence because some bronchodilation is seen within 30 seconds; 50% of maximum response occurs within 3 minutes. Ipratropium bromide is useful as adjunctive therapy in acute severe asthma not completely responsive to SABA alone.[12] Care should be taken when administering ipratropium bromide by nebulizer. If a tight mask or mouthpiece is not used, the ipratropium bromide that deposits in the eyes may produce pupillary dilation and difficulty in accommodation. There is no benefit to continuing combined anticholinergic therapy during hospitalization on the duration of stay or clinical outcomes.[12] In patients with persistent asthma who are intolerant to adverse effects from short-acting β_2-agonists may be prescribed ipratropium for rescue inhaler use.

Tiotropium bromide and umeclidinium bromide are long-acting inhaled anticholinergics with a duration of 24 hours. Tiotropium may be considered an add-on therapy in patients whose asthma is not well controlled with a medium-to-high dose of ICS and LABA combination therapy per the GINA guidelines in those 6 years and older and in those 12 years and older per the 2020 Asthma Focused Updates.[11,12] The addition of tiotropium modestly improves lung function and severe exacerbation requiring oral corticosteroid treatment.[11,12] Umeclidinium bromide is available as a combination inhaler with fluticasone and vilanterol and is indicated in patients aged 18 years and older.

Leukotriene Modifiers

Two cysteinyl LTRAs (zafirlukast and montelukast) and one 5-lipoxygenase inhibitor (zileuton) are available in the United States. These drugs have modest effects on bronchodilation, lung function, exacerbation frequency, and exercise-induced bronchoconstriction; patients with aspirin-induced asthma may benefit.[2] Clinical use of zileuton is limited due to the potential for elevated liver enzymes (especially in the first 3 months of therapy), and the potential inhibition of drugs metabolized by the CYP3A4 isoenzymes. They are not preferred alternatives in mild persistent asthma nor as alternative add-on therapy for moderate persistent asthma (see Tables 44-3 and Table 44-4).[11,12]

One major advantage of the LT modifiers is that they are effective orally, and can be administered once or twice a day. However, they are less effective in asthma than low doses of ICSs.[11,12] Although montelukast is approved for EIB in adults, it is significantly less effective than SABA. They are not as effective as LABAs when added to ICSs for moderate persistent asthma.[11,12] It is not yet possible to assuredly predict which patients respond best to LT modifiers, although there is some evidence that patients with aspirin-sensitive asthma do well. Other predictors may include pre-school age, females, short duration of disease, minimal atopy, high cotinine levels, or high urinary LTE4 levels may respond favorably.[59] It is possible that genetic polymorphisms in the 5-lipoxygenase or LTC_4 synthase pathways or in cys-LT_1 receptors might predict better responders in the future.[59]

The use of montelukast and zafirlukast has fallen out of favor due to the increased observance of unusual adverse effects and modest therapeutic efficacy. Eosinophilic granulomatosis with polyangiitis (formerly known as Churg–Strauss syndrome) is a rare antineutrophil cytoplasmic antibody vasculitis characterized by eosinophil involvement and granulomatous necrotizing effects on small and medium vessels.[60] Other inflammatory skin reactions have been reported that resolve upon discontinuation of montelukast.[60]

Also worrisome are reports of adverse neuropsychiatric events which resulted in the FDA issuing mental health warnings with the use of montelukast beginning in 2008 and updated in 2009 and, most recently, in 2020. In children, the relative risk of neuropsychiatric adverse reactions associated with montelukast is 12 times greater than with ICS.[61] The risks are greatest within a few weeks of starting therapy, resulting in approximately 16% of children discontinuing therapy. Therefore, patients should be closely monitored when initiating treatment with montelukast.[61] The most frequently reported reactions are irritability, aggressiveness, and sleep disturbance; suicidality, though rare, has also been reported.[61]

Reports of fatal hepatic failure associated with zafirlukast have prompted an FDA warning for patients to be made aware of signs and symptoms of hepatic dysfunction.

Zileuton can be administered twice daily as controlled-release tablets. Efficacy data are more limited, liver function monitoring is recommended, and drug interactions are reported with warfarin and theophylline.

Biologic Agents

Table 44-10 outlines the available biologic agents as well as the biomarkers predicting therapeutic responses and the biomarkers modulated by therapy.[62] These agents are targeting the IgE pathway (relevant to allergic asthma) or IL-4, IL-13, and IL-5 pathways (relevant to the Th2 pathway and eosinophilic disorders) and are indicated for patients with moderate or severe asthma (depending upon the drug) along with other biomarker or other clinical indicator associated with treatment response. Tezepelumab blocks TSLP and is potentially a first in class drug.

TABLE 44-10

Targeted Biologic Therapies for Asthma and Potential Biomarkers

Pathway	Biologic Agents Approved	Biomarkers Predicting Therapeutic Response	Route of Administration
IgE	Omalizumab	FeNO Blood eosinophils	Subcutaneous
IL-5	Mepolizumab Reslizumab	Blood eosinophils	Mepolizumab: subcutan eous Reslizumab: intravenous
IL-5Rα	Benralizumab	Blood eosinophils	Subcutaneous
IL-4Rα(IL-4/IL-13)	Dupilumab	Blood eosinophils	Subcutaneous
TSLP	Tezepelumab	–	Subcutaneous

CRTh2, chemoattractant receptor-homologous molecule expressed on Th2 cells; FeNO, the fraction of exhaled nitric oxide; Ig, immunoglobulin; IL, interleukin; R, receptor; TSLP, thymic stromal lymphopoietin.

Data from Reference 63.

These products are typically reserved for patients with moderate-to-severe persistent asthma who have poor symptom control despite treatment on high-dose ICS-LABA with relevant allergic (or eosinophilic) biomarkers or need maintenance oral corticosteroids. Defining which patients have severe asthma and are candidates for biologic therapy consideration is important. The European Respiratory Society (ERS) and the American Thoracic Society (ATS) define severe asthma as “asthma which requires treatment with high-dose inhaled corticosteroids plus a second controller (and/or systemic corticosteroids) to prevent it from becoming ‘uncontrolled’ or which remains uncontrolled despite this therapy”.[64] According to the GINA guidelines approximately, 3% to 10% of people with asthma have severe disease.[2]

The 2020 Asthma Focused Updates did not include an evaluation of biologic therapy because at the time the topics were identified, the only biologic available was omalizumab. GINA provides step-wise guidance for treating difficult-to-treat asthma, which after optimizing management delineates patients with severe asthma and when to consider add-on biologic treatment.[12] Having severe asthma incurs significant healthcare costs.[12] Affordability, availability, predictors of response, and patient preferences should be considered prior to the selection of a biologic agent. Eligibility for biologic therapy will also be determined by age and other specific criteria. In general, criteria for most biologic studies have included pre-bronchodilator FEV_1 between 40% and 80% of predicted and one or more exacerbations in the past year despite moderate-to-high dose ICS.[65] Although some biologics are available for use in children younger than 12 years, limited numbers of pediatric patients have been included in trials. After the biologic agent is initiated, a trial of at least four months is recommended. If the trial results in an unclear response, the trial should be continued for 6 to 12 months, and for those with little to no response, a different biologic should be considered (if eligible). In those patients demonstrating a positive response, biologic therapy should continue and be reassessed every 3 to 6 months. With each assessment, considerations for decreasing or stopping oral corticosteroid therapy first and then other inhaled treatments are recommended, though patients should be on at least a moderate ICS dose. Testing for parasitic infections should be considered prior to starting biologic therapy as these infections can cause blood eosinophilia and untreated infections with a biologic on board can lead to disseminated disease.[12]

Anti-IgE

Omalizumab is a recombinant anti-IgE antibody approved for the treatment of allergic asthma not well controlled on oral corticosteroids or ICSs.[66] It is a humanized monoclonal antibody directed at IgE. Omalizumab binds to the Fc portion of the IgE antibody preventing the binding of IgE to its high-affinity receptor (FcεRI) on mast cells and basophils.[65] The decreased binding of IgE on the surface of mast cells leads to a decrease in the release of mediators in response to allergen exposure.

Omalizumab is administered subcutaneously every 2 to 4 weeks and the dosage is determined by the patient’s baseline total serum IgE level (international units per milliliter [kIU/L]) and body weight (kilograms).[12] Treatment must be administered in a clinical setting for observation for anaphylaxis after each dose, so patient selection must be judicious to ensure commitment to therapy. Omalizumab is currently recommended for the treatment in patients greater than 6 years of age with moderate-to-severe asthma, which is not adequately controlled by ICS, ICS-LABA, and in some cases, oral corticosteroids. Elevated levels of FeNO (24 ppb or greater) and eosinophil levels greater than 260 eosinophils/µg/L while taking high dose ICS are predictive of exacerbation reduction response.[2]

Omalizumab is the biological agent with the greatest safety data in children and long-term safety data has been reassuring.[65] Patients taking omalizumab reported local injection site reactions (similar to all subcutaneous biologics) and rates of anaphylaxis at 0.1% which carries a Boxed Warning. Initial reports indicated increases in malignant neoplasms, however, observational studies have shown rates similar to placebo.

Anti-IL-5

Mepolizumab and reslizumab target IL-5 which regulates the terminal differentiation of eosinophils as well as eosinophil activation and recruitment to the airway.[65] These drugs are monoclonal antibodies directed against IL-5 to block activation of the IL-5 receptor on eosinophils. Benralizumab binds to the alpha subunit of the IL-5 receptor of eosinophils and prevents the binding of IL-5, thus mitigating downstream eosinophilic inflammation.[65]

Mepolizumab is approved for children 6 years and older and has demonstrated long-term safety data in children aged 6 to 11 years.[65] Benralizumab is approved for patients aged 12 years and older; reslizumab is approved for those with severe asthma, 18 years and older, and is the only biologic available that is administered intravenously. Mepolizumab and reslizumab are dosed every 4 weeks; benralizumab is dosed every 4 weeks for 3 months then every 8 weeks. Doses are to be administered in a healthcare setting by professionals who are prepared to manage anaphylaxis. Each of these drugs is indicated for patients with an “eosinophilic phenotype” which has not been formally defined by the FDA or any professional society. However, reductions in exacerbation rate of approximately 50% is observed when patients have a certain minimum peripheral blood eosinophil count which varies by drug.[65] Blood eosinophil counts may be a better predictor of response compared with sputum (airway) eosinophil numbers (airway eosinophils are the ideal biomarker but are difficult to measure clinically).[65] Responsiveness to exacerbation reduction appears to be more likely with blood eosinophil levels above 150 cells/μL (0.15×10^9/L) with mepolizumab, above 400 cells/μL (0.4×10^9/L) with reslizumab, and above 300 cells/μL (0.3×10^9/L) for benralizumab.[65] Benefits in reduced exacerbation rate have been observed in patients who require daily oral corticosteroid therapy while also having an oral corticosteroid-sparing effect.[65]

Patients aged 50 years or older who are to be treated with mepolizumab should receive a recombinant zoster vaccination (preferably not a live virus) 4 weeks prior to starting treatment.[65] Similar to omalizumab, reslizumab had some initial concerns with malignancy that have been mitigated by event rates similar to placebo. Also, as intravenous therapy, the risk of anaphylaxis is higher with reslizumab and includes a Boxed Warning. In addition to injection site reactions, common adverse effects for all three include respiratory tract infections, headache, and asthma worsening.[65]

Anti-IL-4/IL-13 (Dupilumab)

Dupilumab targets the IL-4α receptor, thus blocking IL4 and IL-13 signaling which are key cytokines that promote IgE synthesis and inflammatory cell recruitment. Dupilumab is approved for patients with moderate-to-severe asthma aged 12 years and older with an eosinophilic phenotype and is administered subcutaneously every 2 weeks. Unlike mepolizumab, reslizumab, and benralizumab, FeNO levels above 25 ppb in addition to blood eosinophil levels of at least 150 cells/μL (0.15×10^9/L) is predictive of a response in reducing asthma exacerbation rate by approximately 50%; in those on maintenance OCS, it reduces exacerbation rate and maintenance oral corticosteroid doses.[65] Injection site reactions with dupilumab are relatively higher compared to other biologic agents. Patients have also developed eosinophilia (>3,000 cells/μg/L) and patients should be monitored for vasculitic-appearing rashes, worsening pulmonary or cardiac symptoms, or neuropathy with peripheral eosinophilia.[65]

Magnesium Sulfate

Intravenous and nebulized magnesium sulfate have been used in addition to standard therapies (β_2- agonists, systemic corticosteroids, anticholinergics, and oxygen) in children and adults with severe or life-threatening asthma. Magnesium sulfate is a moderately potent bronchodilator, producing relaxation of smooth muscle by blocking calcium ion influx into smooth muscles and it may have anti-inflammatory effects.[44] For patients with severe asthma exacerbations, current guidelines suggest that a single 2 g intravenous infusion can be helpful in reducing hospital admissions in adults who have an FEV_1 less than 25% to 30% predicted upon arrival in the ED, children and adults who have persistent hypoxemia after standard treatment, and children whose FEV_1 remains below 60% predicted after 1 hour of standard treatment (Evidence A).[12] There appears to be little benefit to adding intravenous or nebulized magnesium in patients with less severe asthma.[12] In children 2 years and older with acute severe asthma and symptoms for 6 hours or less, nebulized (or intravenous) magnesium may be considered during the first hour of standard treatment with nebulized albuterol plus ipratropium.[12] The adverse effects of magnesium sulfate include hypotension, facial flushing, sweating, depressed deep tendon reflexes, hypothermia, cardiac, CNS, and respiratory depression.

Methylxanthines

Methylxanthines have been used for asthma therapy for more than 50 years, but are rarely used owing to the high risk of severe life-threatening toxicity and numerous drug interactions, as well as decreased efficacy compared with ICSs, LABAs, and biologics. Theophylline, the primary methylxanthine of interest, is a moderately potent bronchodilator with mild anti-inflammatory properties and is available for oral and intravenous administration but is not recommended in the GINA guidelines for acute exacerbations or persistent asthma.[12]

Theophylline has a log-linear dose-response curve and dosing requires monitoring of blood concentrations for both efficacy and toxicity (excessive blood concentrations can cause seizures and death). In addition, theophylline is eliminated primarily by metabolism via the hepatic CYP 450 mixed-function oxidase microsomal enzymes (primarily the CYP1A2 and CYP3A4 isozymes), and drug interactions affecting metabolism will significantly affect blood concentrations (see Table 44-11).

TABLE 44-11

Factors Affecting Theophylline Clearance

Decreased Clearance	% Decrease	Increased Clearance	% Increase
Cimetidine	−25 to −60	Rifampin	+53
Macrolides: erythromycin, TAO, clarithromycin	−25 to −50	Carbamazepine	+50
		Phenobarbital	+34
		Phenytoin	+70
Allopurinol	−20	Charcoal-broiled meat	+30
Propranolol	−30		
Quinolones ciprofloxacin, enoxa	−20 to −50	High-protein diet	+25
cin, perfloxacin		Smoking	+40
Interferon	−50	Sulfinpyrazone	+22
Thiabendazole	−65	Moricizine	+50
Ticlopidine	−25	Aminoglutethimide	+50
Zileuton	−35		
Systemic viral illness	−10 to −50		

Alternative Therapies

Complementary therapies that patients might report using include acupuncture, homeopathy, herbal medicines, ayurvedic medicine, ionizers, osteopathy, and chiropractic manipulations. However, there are no studies of sufficient rigor to assess their efficacy.[2] Breathing and relaxation exercises have shown to provide small improvements in symptoms, quality of life, and psychological outcomes but not in exacerbation frequency.[2] Benefits may be due to relaxation effects, voluntary reduction in SABA use, and engagement in self-care, but the costs of certain intervention measures may be expensive.[2] In patients with low serum levels of Vitamin D, supplementation may be effective in reducing exacerbations requiring systemic corticosteroids (high-quality evidence).[2] Vitamin D is an inexpensive treatment alternative that may be useful only in those who are Vitamin D deficient.[2] There is little evidence to support using immunosuppressants such as methotrexate due to marginal steroid-sparing effects and the risk of significantly severe adverse effects.[2]

General Principles of Aerosol Therapy for Asthma

④ ⑤ Aerosol delivery of drugs for asthma has the advantage of being site-specific and thus enhancing the therapeutic ratio. Inhalation of short-acting β_2-agonists provides more rapid bronchodilation than either parenteral or oral administration, as well as the greatest degree of protection against EIB and other challenges.[46] ICSs have been developed with rapid oral and systemic clearance to enhance lung activity and reduce systemic activity.[52] Specific agents (eg, formoterol, salmeterol, and ipratropium bromide) are only effective by inhalation. Therefore, an understanding of aerosol drug delivery is essential to optimal asthma therapy. Table 44-12 lists the factors determining lung deposition of therapeutic aerosols.

TABLE 44-12

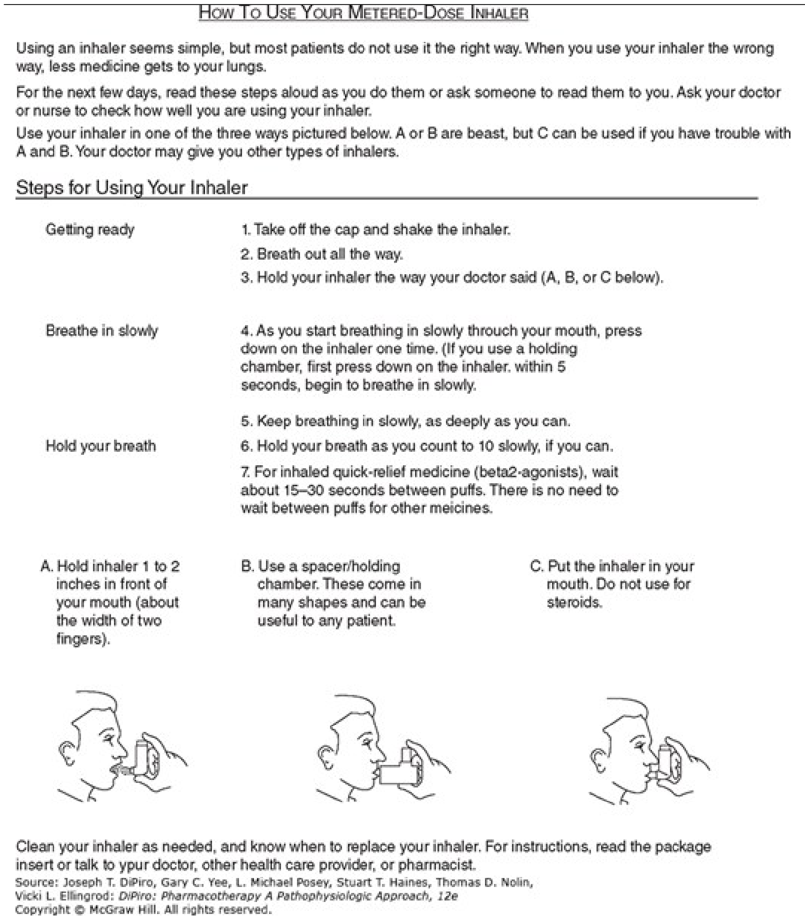
Factors Determining Lung Deposition of Aerosols

Device	Device Factors	Patient Factors
Metered-dose inhaler (MDI)	Canister held inverted Formulation (solution or suspension) Actuator cleanliness Addition of a spacer device	Inspiratory flow (slow, deep) Breath-holding Tilting head back Coordinating actuation with inhalation Priming and shaking the device
Dry powder inhaler (DPI)	Device cleanliness Resistance to inhalation Humidity	Inspiratory flow (deep, forceful) Tilting head back Maintaining parallel to ground once activated
Jet nebulizer (small volume)	Volume fill (3-6 mL) Gas flow (6-12 L/min) Dead space volume Open vs closed system Thumb-activating valve Mouthpiece vs face mask	Inspiratory flow (slow, deep) Breath-holding Tapping nebulizer
Ultrasonic nebulizer	Volume fill Not effective for suspensions Mouthpiece vs face mask	Inspiratory flow (slow, deep) Breath-holding Tapping nebulizer
Spacer device	Volume (≥650 mL) One-way valves Holding chamber vs open-ended Antistatic lining Mouthpiece vs face mask	Inspiratory flow (slow, deep) Time between actuation and inhalation (<5 seconds) Cleaning with detergent to reduce static Multiple actuations (all at once) decrease delivery Coordination of actuation and inhalation for the simple open-tube spacers

Using the appropriate inhalation technique is essential to achieving optimal drug delivery and therapeutic effect.[12] The components are illustrated in Fig. 44-9. Approximately 50% to 80% of a dose from MDIs and DPIs deposits on the oropharynx and is then swallowed; the rest is either left in the device or exhaled.[67] It is important that MDI actuation occurs during inhalation.[67] Many patients do not use their MDIs optimally, and patient instruction with demonstration is the most effective means of improving inhaler technique.[12] Even with instruction, up to 80% of patients, particularly young children and older adults, cannot master the use of an MDI.[12] For these patients, attachment of a VHC to the MDI can improve efficacy significantly. However, the addition of a VHC offers no advantage in patients who can use an MDI optimally alone.[67] Mouth rinsing following treatment with MDI- and DPI-ICSs is important to minimize local adverse effects and oral absorption.[12]

FIGURE 44-9

Instructions for inhaler use. (Reprinted from NIH Publication No. 07-4051. Expert Panel Report 3: Guidelines for the Diagnosis and Management of AsthmaFull Report 2007).



HOW TO USE YOUR METERED-DOSE INHALER

Using an inhaler seems simple, but most patients do not use it the right way. When you use your inhaler the wrong way, less medicine gets to your lungs.

For the next few days, read these steps aloud as you do them or ask someone to read them to you. Ask your doctor or nurse to check how well you are using your inhaler.

Use your inhaler in one of the three ways pictured below. A or B are beast, but C can be used if you have trouble with A and B. Your doctor may give you other types of inhalers.

Steps for Using Your Inhaler

Getting ready	1. Take off the cap and shake the inhaler. 2. Breath out all the way. 3. Hold your inhaler the way your doctor said (A, B, or C below).
Breathe in slowly	4. As you start breathing in slowly throuch your mouth, press down on the inhaler one time. (If you use a holding chamber, first press down on the inhaler. within 5 seconds, begin to breathe in slowly. 5. Keep breathing in slowly, as deeply as you can.
Hold your breath	6. Hold your breath as you count to 10 slowly, if you can. 7. For inhaled quick-relief medicine (beta2-agonists), wait about 15–30 seconds between puffs. There is no need to wait between puffs for other meicines.

A. Hold inhaler 1 to 2 inches in front of your mouth (about the width of two fingers).

B. Use a spacer/holding chamber. These come in many shapes and can be useful to any patient.

C. Put the inhaler in your mouth. Do not use for steroids.

Clean your inhaler as needed, and know when to replace your inhaler. For instructions, read the package insert or talk to ypur doctor, other health care provider, or pharmacist.

Medication Delivery: Device Determinants

Devices used to generate therapeutic aerosols include jet nebulizers, ultrasonic nebulizers, MDIs, and DPIs. The single most important device factor determining the site of aerosol deposition is particle size.[67] Devices for delivering therapeutic aerosols generate particles with mass median aerodynamic diameters (MMAD) from 0.5 to 35 μm.[67] Particles larger than 10 μm deposit in the oropharynx, particles between 5 and 10 μm deposit in the trachea and large bronchi, particles 1 to 5 μm in size reach the lower airways, and particles smaller than 0.5 μm act as a gas and are exhaled. The available MDIs, particularly for corticosteroid inhalers, are solution aerosols (vs suspensions) with extra-fine particle size distributions (MMAD of 1.1 μm) and high lung deposition.

In asthma, the target for drug delivery is the airways and not the alveoli. Respirable particles are deposited in the airways by three mechanisms: (a) inertial impaction, (b) gravitational sedimentation, and (c) Brownian diffusion.[67] The first two mechanisms are the most important for therapeutic aerosols and probably are the only factors that can be manipulated by patient technique.

Each delivery device within a classification generates specific aerosol characteristics, so the extrapolation of delivery data from one device cannot be applied to the other devices in the class. For instance, MDIs can deliver 15% to 50% of the actuated dose; DPIs, 10% to 30% of the labeled dose; and nebulizers 2% to 15% of the starting dose.[67] MDIs and DPIs are portable and convenient, unlike jet nebulizers. Small portable ultrasonic nebulizers have also been developed.

MDIs consist of a pressurized canister with a metering valve; the canister contains the active drug, low-vapor-pressure propellants such as HFA, co-solvents, and/or surfactants.[67] With any change in the components of an MDI, the FDA considers it to be a new drug that requires stability, safety, and efficacy studies prior to approval. The MDI drug is either in solution or a suspended micronized powder. In order to disperse the suspension for accurate delivery, the canister must be shaken. The metering chamber measures a liquid volume, and, therefore, the device must be held with the valve stem downward so that the chamber is covered with liquid[67] (Fig. 44-10). If not used for a period of time the drug in the chamber evaporates which could lead to an inadequate therapeutic dose. Some inhalers have to be primed before first use to fill the chamber and after an interval of nonuse.[67] When the canister is actuated, the device releases the propellant and drug in a forceful spray whose particles are large (MMAD = 45 μm)[67] (see Fig. 44-10). As evaporation occurs, the particle size is reduced to a final MMAD of 0.5 to 5.5 μm depending on the MDI. The aerosol-cloud extends about 6 inches beyond the MDI at the lowest MMAD.[67] Each MDI has different conditions for storage, priming, and durations to expiration, so the clinician must become familiar with and counsel the patient on these factors.

FIGURE 44-10

Illustration of a metered-dose inhaler demonstrating the particle size difference as the aerosol-cloud extends outward.

Spacer devices are used frequently with an MDI to decrease oropharyngeal deposition and enhance lung delivery.[12] However, not all spacer devices produce similar effects. The design of spacers varies from simple open-ended tubes that separate the MDI from the mouth to the VHC with one-way valves that open during inhalation (the preferred system); some VHCs have a face mask to accommodate drug delivery in children 5 years or younger. A VHC allows evaporation of the propellant prior to inhalation permitting a greater number of drug particles to achieve a respirable droplet size. VHC use also allows inhalation after actuation of the MDI, obviating the need for good hand-lung coordination.[67] Additionally, the large particles that normally would deposit in the oropharynx “rain out” in the spacer.[67] Spacer size may affect the amount of drug available for inhalation; a lower volume spacer (less than 350 mL) is advantageous in very young children.[12]

All the available spacers significantly reduce oropharyngeal deposition from MDIs, with the VHCs being superior to the open-ended tubes.[67] Reducing oropharyngeal deposits is an important factor in reducing local adverse effects (eg, hoarseness and oropharyngeal candidiasis) from ICSs.[67] The change in lung delivery depends on both the MDI and the drug, where one spacer device may enhance delivery with one MDI preparation and decrease delivery with others.[67] Therefore, once a patient is stabilized on a drug and chamber combination, the chamber should not be substituted in order to avoid changes in the dose delivered to the lungs. Finally, over time, holding chambers (eg, plastic) can build up static electricity that attracts small particles to the sides of the chamber, significantly reducing aerosol availability. Some spacers should be washed with household detergent with a single rinse and allowed to drip dry.[12] Other VHCs have been developed with antistatic materials.

Dry micronized powders can be inhaled directly into the lungs. A number of DPIs are now available for use in the United States.[67] Each DPI has unique characteristics with advantages and disadvantages (Table 44-13). The primary advantage of DPIs is that they are breath-actuated and require minimal hand-lung coordination, and it is thus easier to teach patients proper technique.[67] Some DPIs are more flow dependent than others.[67] Thus, similar to MDIs and spacers, delivery data from one DPI cannot be extrapolated to another.

TABLE 44-13

Characteristics of Commonly Used Inhalation Devices

Device	Drugs	Breath Activated	Dose Counter	Other Excipients	Disadvantages
MDI	All classes	No	No/yes	Propellants, surfactants, cosolvents	Requires coordination of actuation and inhalation. Large pharyngeal deposition. Difficult to teach. Priming and cleaning considerations.
Pressair (DPI)	Aclidinium	Yes	Yes	Lactose filler	Requires rapid inhalation to activate
Respiclick (DPI)	Albuterol	Yes	Yes	Lactose filler	Requires rapid inhalation to activate
MDI plus valved holding chamber	All classes	No	No		More expensive than MDI alone; less portable; some payers will not pay; inconsistent effect on delivery; nonstatic prefer red
Jet nebulizers	All classes	No	—	Preservatives in some solutions	Significant Interbrand variability; expensive and time-consuming; less efficient than MDIs; contamination possible; preparations may be light and temperature-sensitive (short shelf life)
Ultrasonic nebulizer	Cromolyn solution, short-acting β_2-agonist solutions	No	—	Preservatives in some solutions	Same as for jet nebulizers and cannot be used for suspensions; battery operated are portable
Flexhaler (DPI)	Budesonide	Yes	Yes	Lactose filler	Requires high inspiratory flow (60 L/min)
					Pharyngeal deposition
					Not approved for <6 years of age
Diskus (DPI)	Fluticasone; salmeterol; fluticasone/salmeterol	Yes	Yes	Lactose filler	Not approved for <4 years of age
					Requires inspiratory flow of 30-60 L/min
Ellipta (DPI)	Fluticasone furoate Fluticasone/vilanterol	Yes	Yes	Lactose filler	Not approved for <12 years of age (18 years for fluti casone/vilanterol)
					Requires inspiratory flow of 60 L/min
Aerolizer (DPI)	Formoterol	Yes	—	Lactose filler	Single-dose capsules. Not approved for <5 years of age
					Requires flow of 30-60 L/min
Neohaler (DPI)	Indacaterol	Yes	—	Lactose filler	Single-dose capsules. Not approved for children Requires flow of 60 L/min

Handihaler (DPI)	Tiotropium	Yes	—	Lactose filler	Single-dose capsule. Not approved for children. Requires flow of 20 L/min. Not FDA approved in asthma.
Twisthaler (DPI)	Mometasone	Yes	Yes	Lactose filler	Not approved for <4 years of age
Respimat (SMI)	Tiotropium Albuterol/Ipratropium Olodaterol	No	Yes	Preservative	Requires slow deep breath. Not approved for <12 years of age

Reported adherence to inhaled asthma medications has been less than 50% for adolescents and adults.[68] Adherence barriers are different in each patient population and should include a personalized approach. Device ease-of-use and ability to perform proper inhaler technique should be considered and assessed. Electronic sensors either attached to or integrated with MDIs and DPIs used in conjunction with smartphone applications have been developed to track and promote adherence. Although these technological advances will likely become commonplace in the future, the current cost (~$300 per device or for a 1-year subscription) for these devices and monitoring services are a significant barrier.

Nebulizer devices come in two basic types: the jet nebulizer and the ultrasonic nebulizer. Jet nebulizers produce an aerosol from a liquid solution or suspension placed in a cup. A tube connected to a stream of compressed air or O_2 flows up through the bottom and draws the liquid up an adjacent open-ended tube.[67] The air and liquid strike a baffle, creating a droplet cloud that is then inhaled.[67] Ultrasonic nebulizers produce an aerosol by vibrating liquid lying above a transducer at speeds of about 1 MHz.[67] Both produce similar degrees of lung deposition, with the exception that ultrasonic nebulizers are ineffective for nebulizing currently available micronized suspensions.[67] The aerosol output and lung delivery vary significantly among the commercially available jet nebulizers even when operated in the same manner.[67] Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to nebulize the dose.[67] The MMAD of the droplets is related directly to the gas flow, with flows of 5 to 12 L/min providing an aerosol cloud with an MMAD of 4 to 8 μm for most jet nebulizers.[67] Each jet nebulizer comes with optimal operating and cleaning instructions.

Medication Delivery: Patient Determinants

⑥ ⑦ The most important patient factor determining aerosol deposition is inspiratory flow (see Table 44-12).[67] High inspiratory flows with MDIs increase the degree of deposition owing to impaction of particles of any size, thereby increasing deposition centrally (ie, throat and large airways) and decreasing peripheral deposition. The optimal inspiratory flow for most MDIs is slow and deep (approximately 30 L/min or 5 seconds for a full inhalation).[67] In general, DPIs require higher inspiratory flows (greater than or equal to 60 L/min) and a change in inhalation technique (ie, deep, forceful inspiration) for optimal dispersion of the powder, which, in turn, increases the amount of drug delivered to the larger central airways.[67] Patients should be cautioned not to exhale into DPIs because this causes loss of dose and moistens the dry powder, causing aggregation into larger particles. Patient factors that cannot be controlled include interpatient variability in airway geometry (particularly the differences between children and adults)[67] and the effects of bronchospasm, edema, and mucus hypersecretion. Mild obstruction increases aerosol deposition; however, severe obstruction probably leads to increased central deposition from impaction.[67] The absolute delivery to the lung is not as important as the consistency of delivery, assuming that a sufficient dose to produce the desired therapeutic effect is achieved. No single inhalation device is the best for all patients. Table 44-13 lists the differing characteristics of inhalation devices.

Delivery from high-resistance DPIs is more flow dependent than from low-resistance DPIs. Thus, younger children and possibly older adults will have more variability in delivery from high-resistance devices.[67] Most children younger than 4 years of age cannot generate a sufficient inspiratory flow to use DPIs. Young children (younger than 4 years) and infants generally require the use of a face mask attached to either an MDI plus VHC or a nebulizer. The use of a face mask results in a reduction in lung delivery due to the portion of the aerosol inhaled nasally, so the doses of drugs used in these patients are often not decreased.

EVALUATION OF THERAPEUTIC OUTCOMES

The two domains of asthma control are "symptom control" and "future risk of adverse outcomes."[12] Symptom control is assessed by asking about the frequency of daytime and night-time asthma symptoms, reliever medication use, and activity limitations. Poor symptom control is also an indicator of future risk for exacerbations.[12] However, even when perceived symptom control is good, an assessment of the future risk of exacerbations is critical. Determining the risk of future adverse patient outcomes includes assessment of the risk of future exacerbations, fixed airflow limitation (and thus diminished response to therapy), and medication adverse effects.[12] To assess the risk for future exacerbations (defined as a worsening of asthma requiring the use of systemic corticosteroids or an increase in the use of systemic corticosteroids), lung function should be measured before the start of treatment and then 2 months later when the maximum response to controller medications is likely attained.[12] This benchmark of "personal best" can then be used for ongoing risk assessment. Other factors that affect future risk of exacerbations include exacerbation history in the previous year (define as one or more exacerbations requiring systemic corticosteroids is a risk factor), history of intubation or intensive care unit stay for asthma, or asthma-related ED visits for urgent care.[12] Fixed airflow limitation can be affected by lack of ICS treatment, smoking exposure, and poor lung function. During ongoing care, spirometry should be measured yearly but long-term PEF monitoring is typically reserved for those with severe asthma.[12] The risk of adverse effects is influenced by oral drug administration, ICS dose, and potential drug interactions with cytochrome P450 inhibitors.[12] In addition, poor inhaler technique (such as not rinsing and spitting after ICS use) can lead to oral candidiasis or an increase in the swallowed fraction of the dose that could influence linear growth in children.

There are several simple screening questionnaires that can be used to assess asthma symptom control quickly in a clinic setting. The Asthma Control Test is a validated simple five-question survey for patients 12 years and older that yields a numerical score; a score of 19 or less indicates poor asthma control and several institutions have incorporated the survey into the electronic health record in order to evaluate changes over time.[12] There is a companion Childhood Asthma Control Test survey for children 4 to 11 years.[12] A number of other validated questionnaires exist such as the Asthma Control Questionnaire (ACQ) and the Test for Respiratory and Asthma Control in Kids (TRACK).[12]

Patients should also be asked about exercise tolerance but perceived good exercise tolerance may be biased by a sedentary lifestyle due to frequent bothersome symptoms. All patients on inhaled drugs should have their inhalation delivery technique evaluated periodically—monthly initially and then every 3 to 6 months. Before stepping up therapy, adherence, environmental factors, and comorbid conditions should be reviewed.[12]

Following initiation of anti-inflammatory therapy or an increase in dosage, most patients should begin experiencing a decrease in symptoms in 1 to 2 weeks and achieve maximum improvement within 4 to 8 weeks. The use of higher ICS doses or more potent agents may accelerate symptom improvement. Increases in FEV_1 and PEF should follow a similar time frame; however, a decrease in BHR, as measured by morning PEF, PEF variability, and exercise tolerance, may take 1 to 3 months.[12] Patients should be informed that following a viral respiratory infection, they may experience decreased exercise tolerance for up to 4 weeks.

Initial visits with the patient should focus on the patient's concerns, expectations, and goals of treatment. Initial patient education should focus on asthma as a chronic lung disease, the types of medications, how they are to be used including inhaler technique, and when to seek medical advice. Written action plans should be provided. Both peak flow-based and symptom-based self-monitoring plans can be effective.[12] The first follow-up visit should include a repetition of the educational messages from the first visit, as well as a review of the patient's current medications, adherence, barriers, and challenges.

CONCLUSION

Asthma is a complex disease with a multitude of clinical presentations. The exact defect in asthma has not been defined, and it may be that asthma is a common presentation of a heterogeneous group of diseases. Asthma is defined and characterized by excessive reactivity of the bronchial tree to a wide variety of noxious stimuli. The reaction is characterized by bronchospasm, excessive mucus production, and inflammation. The central role of inflammation in inducing and maintaining BHR is now becoming widely appreciated. The goal of asthma therapy is to normalize, as much as possible, the patient's life and prevent chronic irreversible lung changes. Drugs are the mainstay of asthma management. The goal of drug therapy is to use the minimum amount of medications possible to control the disease. In persistent asthma, therapy should be aimed at both bronchospasm and inflammation in order to produce the best results. Patients should be followed and monitored diligently for toxicities. Although death from asthma is an uncommon event, the most common cause of death is under-estimating the severity of obstruction either by the patient or by the clinician; the next common cause is under-treatment. A cornerstone of therapy is education and the realization that most asthma deaths are avoidable.

ABBREVIATIONS

ACOS	Asthma COPD Overlap Syndrome
ACQ	Asthma Control Questionnaire
ACTH	adrenocorticotropic hormone
Arg	arginine
BHR	bronchial hyper-responsiveness
CFC	chlorofluorocarbon
COPD	chronic obstructive pulmonary disease
CYP	cytochrome P450
DPI	dry powder inhaler
ED	emergency department
EIB	exercise-induced bronchospasm
EPR3	Expert Panel Report 3
FeNO	fraction of exhaled nitric oxide
FEV_1	forced expiratory volume in 1 second
FVC	forced vital capacity
GERD	gastroesophageal reflux disease
GINA	Global Initiative for Asthma
GM-CSF	granulocyte-macrophage colony-stimulating factor
HFA	hydrofluoroalkane
HPA	hypothalamic-pituitary–adrenal
ICAM-1	intercellular adhesion molecule 1
ICS	inhaled corticosteroid
IFN-γ	interferon-γ

IgE	immunoglobulin E
IL	interleukin
iNOS	inducible nitric oxide synthase
LABA	long-acting inhaled β$_2$-agonist
LAMA	long-acting muscarinic antagonist
LT	leukotriene
MDI	metered-dose inhaler
MMAD	mass median aerodynamic diameter
NAEPP	National Asthma Education and Prevention Program
NANC	nonadrenergic, noncholinergic
NO	nitric oxide
O_2	oxygen
PAF	platelet-activating factor
PEF	peak expiratory flow
RCT	randomized controlled trial
RSV	respiratory syncytial virus
SABA	short-acting beta-agonist
T-cells	thymically derived lymphocytes
Th_1	type 1 T-helper cell
Th_2	type 2 T-helper cell
TSLP	thymic stromal lymphopoietin
VCAM-1	vascular cell adhesion molecule 1
VHC	valved holding chamber
VIP	vasoactive intestinal peptide

SELF-ASSESSMENT QUESTIONS

1. The aerosol particle size most likely to deposit in the lower airways is:

   A. 10-20 µm

   B. 5-10 µm

   C. 1-5 µm

   D. 0.1-0.5 µm

2. Advantages of spacer devices include all of the following EXCEPT:

   A. Enhanced lung delivery

   B. Decreased oropharyngeal deposition of drug

   C. Increased percent of drug particles achieving respirable droplet size

   D. Standardization of spacers to make them substitutable

3. An objective assessment used to monitor response to therapy in an acute severe asthma exacerbation include which one of the following:

   A. Fraction of exhaled nitric oxide (FeNO)

   B. Impulse oscillometry

   C. Serum cortisol levels

   D. Pulse oximetry

4. Pharmacologic responses to β_2-agonists include all of the following EXCEPT:

   A. Increased neuromuscular transmission

   B. Smooth muscle relaxation

   C. Stimulate uterine contractions

   D. Vasodilation of the vasculature

5. A protective factor that may prevent the development of asthma includes:

   A. A mother who had a cesarean section

   B. Being obese

   C. Having older siblings

   D. Using antibiotics in childhood

6. Which one of the following statements is CORRECT about the major characteristics of marketed dry powder inhalers (DPIs) used to deliver drugs to the lungs?

   A. Drug delivery is breath-actuated, requiring minimal hand–lung coordination by the patient.

   B. DPI's have been standardized to require the same inspiratory flow rate.

   C. Only inhaled corticosteroids are available as a DPI.

   D. Slow inhalation from the device is needed for optimal lung deposition of the powder.

7. Which one of the following statements is CORRECT concerning the use of leukotriene modifiers in asthma management?

   A. The FDA issued a warning about serious mental health side effects of montelukast.

   B. LTRAs are more effective than LABAs as an add-on to ICS therapy for moderate persistent asthma.

   C. Montelukast has increased efficacy over short-acting inhaled β_2-agonists for the treatment of EIB.

D. The use of leukotriene modifiers is limited due to the potential for renal toxicity.

8. Which one of the following statements is CORRECT concerning biologics in the treatment of asthma?

   A. Omalizumab blocks release of interleukin-5.

   B. Reslizumab is administered subcutaneously.

   C. Mepolizumab response is predicted by baseline blood eosinophil levels.

   D. Dupilumab blocks the IL-5 receptor.

Please refer to the following case vignette to answer Questions 9 and 10.

AB is a 37-year-old female who presents with the following: FEV_1 76% predicted, use of albuterol (for rescue) 5 to 6 days/wk, waking with asthma symptoms four to five times/mo, and increased asthma symptoms during her daily walk to work and workouts. She completed a 5-day course of prednisone 2 months ago. Her only medication is albuterol.

9. AB presents to the emergency room with shortness of breath, wheezing, and speaking in monosyllabic words. What is the best treatment option to initiate?

   A. Albuterol by metered-dose inhaler plus spacer

   B. Albuterol by metered-dose inhaler with spacer and ipratropium bromide with spacer

   C. Albuterol by metered-dose inhaler with spacer and ipratropium bromide with spacer and 40mg of prednisone

   D. Albuterol by metered-dose inhaler wand ipratropium bromide with spacer and 40mg of prednisone plus IV theophylline

10. After discharge from the ED, AB sees her provider a week later. Which of the following would be the most appropriate pharmacologic treatment options for AB?

   A. Continue SABA as needed to control symptoms

   B. Daily low-dose ICS with SABA as needed to control symptoms

   C. ICS-formoterol used daily and as needed for symptoms

   D. Mepolizumab

11. Which one of the following is NOT a mediator associated with airway inflammation?

   A. Histamine

   B. GobleT-cells

   C. Leukotrienes

   D. Prostaglandins

12. Which of the following statements is CORRECT concerning ICS in the treatment of asthma?

   A. Available ICS are equipotent based on a µg to µg comparison.

   B. Advantages are high topical potency and low systemic activity.

   C. Response to therapy is prompt, with resolution of symptoms within 3 to 4 days.

   D. Therapeutic index is irrelevant to the delivery device

13. Regarding LABAs, all of the following are correct EXCEPT:
    - A. These are more β_2 selective and lipid-soluble than albuterol.
    - B. Combination ICS/LABA treatment provides greater asthma control than increasing the dose of ICS alone.
    - C. Tolerance may occur with chronic therapy.
    - D. Onset of action is slower than albuterol, approximately 30 minutes.
14. Which of the following medications does NOT trigger asthma symptoms?
    - A. Aspirin
    - B. Naproxen
    - C. Propranolol
    - D. Penicillin
15. Which one of the following is NOT a dry powder inhaler?
    - A. Diskus
    - B. Flexhaler
    - C. Respimat
    - D. Twisthaler

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Particles smaller than 1-5 µm will be exhaled before reaching the lower airways. Larger particles will be too heavy and deposit in the oropharynx or trachea and large bronchi. The drug needs to reach the lower airways for optimum effect.
2. **D.** Spacers provide enhanced drug delivery by slowing the speed of the drug from the pMDI so that it can flow from the oropharynx into the airways. They also prevent the drug from depositing on the tongue and throat which can result in oral candidiasis with inhaled corticosteroid medications. Spacers also allow some of the propellant to evaporate so that more particles are in the respirable size range.
3. **D.** Pulse oximetry provides an objective assessment of improvements in oxygenation as a result of treatment with β_2-adrenergic receptor agonists and corticosteroids. FeNO is used to measure changes in airway inflammation with the use of controller therapy. Spirometry is a measurement of lung function but is not used in the assessment of acute asthma. Serum cortisol is used to measure the systemic effects of corticosteroids.
4. **C.** The primary effect of β_2-agonists is relaxation of smooth muscle in the airway which results in dilation of the bronchi and improves airflow.
5. **C.** Having older siblings is thought to expose a child to infectious agents that tip the balance in favor of immunologic T-helper type 1 development rather than T-helper cell type 2.
6. **A.** Unlike pMDI in which the actuation of the inhaler must be coordinated with inspiration, dry powder inhalers only typically require sufficient inhalation for adequate lung delivery.
7. **A.** Evidence continues to be published on the neuropsychiatric effects of montelukast. These effects often appear within a few weeks of starting therapy but in some patients may emerge more slowly over several months.

8. **C.** Response to mepolizumab, reslizumab, and benralizumab is dependent upon baseline blood eosinophil levels. Response to dupilumab is dependent upon both baseline blood eosinophil levels and FeNO levels.

9. **C.** AB is having a severe asthma exacerbation and should be treated to rapidly relieve airway obstruction. Patients with severe symptoms should receive both albuterol and ipratropium. Oral corticosteroids should be started within 1 hour. There is no role for IV theophylline for the management of acute exacerbations.

10. **B.** AB's symptoms indicate the need for controller therapy. ICS-formoterol used as a controller and reliever (SMART) has been shown to reduce the risk of exacerbations. Her symptoms suggest she needs more than just a low dose of ICS. Biologics are not indicated until maximal inhaled therapy has been tried and symptoms persist.

11. **B.** GobleT-cells produce mucus in the airway. Histamine, leukotrienes, and prostaglandins are produced by inflammatory cells such as eosinophils, basophils, macrophages, and mast cells.

12. **B.** Inhaled corticosteroids have a beneficial topical-to-systemic ratio compared with oral corticosteroids. Therapy with inhaled corticosteroids may show benefit within a week but requires several months for full benefit to be realized.

13. **D.** Most of the long-acting β_2-adrenergic receptor agonists have an effect within minutes; the exception is salmeterol which has an onset in about 10 minutes.

14. **D.** Aspirin and naproxen can precipitate asthma through cyclooxygenase-1 inhibition and β-blockers can block the β_2-adrenergic receptor and cause bronchoconstriction.

15. **C.** Respimat is a soft mist inhaler.

Chapter 45: Chronic Obstructive Pulmonary Disease

Sharya V. Bourdet; Dennis M. Williams

KEY CONCEPTS

KEY CONCEPTS

① Chronic obstructive pulmonary disease (COPD) is a treatable and preventable disease characterized by progressive airflow limitation that is not fully reversible and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.

② Mortality from COPD has increased steadily over the past three decades; it is the fourth leading cause of death in the United States.

③ The primary cause of COPD is cigarette smoking, implicated in 75% of diagnosed cases in the United States. Other risks include genetic predisposition, environmental exposures (including occupational dust and chemicals), and air pollution.

④ In patients with COPD, staging of airflow limitation (GOLD 1-4) is classified by spirometry measurements. Disease severity (Category A-D) is classified using a combined assessment of symptom score, as measured by a validated questionnaire, and risk for future exacerbations.

⑤ Smoking cessation and avoidance of other known toxins are the only management strategies proven to slow COPD progression.

⑥ Oxygen therapy can reduce mortality in selected patients with COPD. Oxygen therapy is indicated for patients with a resting PaO_2 of less than 55 mm Hg (7.3 kPa) or a PaO_2 of less than 60 mm Hg (8.0 kPa) and evidence of right-sided heart failure, polycythemia, or impaired neurologic function.

⑦ Inhaled bronchodilators are the mainstay of drug therapy for COPD and are used to relieve patient symptoms and improve exercise tolerance and quality of life. Guidelines recommend short-acting bronchodilators as initial therapy for patients with occasional symptoms and all patients as rescue therapy to relieve symptoms.

⑧ For patients experiencing persistent symptoms, either a long-acting β_2-agonist (LABA) or long-acting anticholinergic (LAMA) offers significant benefits, and both are of comparable efficacy. If a patient has continued symptoms, combining long-acting bronchodilator agents (LABA plus LAMA) is recommended.

⑨ For patients at high risk for future exacerbations, either a long-acting β_2-agonist (LABA) or long-acting anticholinergic (LAMA) is effective at reducing exacerbation frequency. Anticholinergic agents are more effective at reducing exacerbation frequency and should be considered first-line. If a patient has continued exacerbations or has more severe disease, combining long-acting bronchodilator agents (LABA plus LAMA) is recommended.

⑩ The role of inhaled corticosteroid (ICS) therapy in COPD is controversial. Patients with frequent and severe exacerbations may benefit from ICS therapy, although the risk of pneumonia is increased.

⑪ Acute exacerbations of COPD (AECOPD) have a significant impact on disease progression and mortality. Treatment of acute exacerbations includes intensification of bronchodilator therapy and a short course of systemic corticosteroids.

⑫ Antimicrobial therapy should generally be used during AECOPD if the patient exhibits at least two of the following: increased dyspnea, increased sputum volume, and increased sputum purulence. A C-reactive protein (CRP) test may be helpful to guide the decision to treat a COPD exacerbation with antibiotics.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled "Pathophysiology of Large and Small Airway Disease in COPD" in AccessPharmacy by Scott Stern, MD. This 5-minute video provides a visual explanation of pathophysiologic changes occurring in lungs of patients with COPD. This video assists with comprehension of physiologic changes and correlation with clinical presentation in COPD.

Watch the video "Gasping for Air: Life with COPD" (*The New York Times*, July 31, 2008). This 6-minute video provides the perspective of a patient diagnosed with COPD. This video helps remind clinicians of patient experiences with the disease, how physiologic changes are correlated with symptoms, and challenges to optimal diagnosis and treatment.

INTRODUCTION

① Chronic obstructive pulmonary disease (COPD) is a common lung disease characterized by airflow limitation that is not fully reversible, in contrast to the reversibility of airflow limitation in asthma. COPD is both chronic and progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.[1] COPD is preventable and treatable and causes significant extrapulmonary effects that contribute to disease severity in a subset of patients.

To standardize the care of patients with COPD and present evidence-based recommendations, the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO) launched the Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2001. The GOLD expert panel revises their recommendations annually, typically in December.[1] The goals of the GOLD organization are to increase awareness of COPD and reduce morbidity and mortality associated with the disease. In addition to GOLD, other international organizations have developed consensus guidelines focusing on preventing and managing acute exacerbations associated with COPD. The American College of Chest Physicians (ACCP) and the Canadian Thoracic Society collaborated on guidelines for the prevention of COPD exacerbations which were published in 2015.[2] In 2017, the American Thoracic Society (ATS) and European Respiratory Society (ERS) jointly published guidelines for both the prevention and management of acute exacerbations of COPD (AECOPD).[3,4]

International guidelines emphasize the terms *preventable* and *treatable* to support a positive approach to managing the patient with COPD. Support is also reflected in advocacy and availability of research funding to improve understanding about this disease and its management. Examples include the creation of the Division of Lung Diseases of the NHLBI to promote and fund multidisciplinary research and collaboration as well as the Centers for Disease Control and Prevention's COPD National Action Plan, which outlines strategic goals for empowering patients and caregivers, preventing and managing disease, supporting research initiatives, and developing educational and public health policies related to COPD.[5,6]

COPD has historically described a group of pulmonary diseases with a fixed airflow limitation. The two principal conditions are chronic bronchitis and emphysema, which are phenotypes. Chronic bronchitis is associated with chronic or recurrent episodes of excessive mucus secretion into the bronchial tree with a cough present on most days for at least 3 months of the year for at least 2 consecutive years in a patient in whom other causes of chronic cough have been excluded.[1] While chronic bronchitis is defined in clinical terms, emphysema is defined in terms of anatomic pathology. Historically, emphysema was diagnosed based on histologic findings at autopsy. Given that this histologic definition has limited clinical value, emphysema also has been defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles accompanied by destruction of their walls without obvious fibrosis.[1]

Differentiating COPD as either chronic bronchitis or emphysema as distinct subsets of COPD is no longer considered relevant because both are caused by a common risk factor (cigarette smoking), and most patients exhibit features of both. Emphasis is placed on the pathophysiologic features of small airways disease and parenchymal destruction as contributors to chronic airflow limitation. Chronic inflammation affects the integrity of the airways, causes damage, and promotes the destruction of the parenchymal structures. The underlying problem is persistent exposure to noxious particles or gases that sustain the inflammatory response. The airways of both the lung and the parenchyma are susceptible to inflammation, and the result is the chronic airflow limitation that characterizes COPD (Fig. 45-1).

EPIDEMIOLOGY

② In the United States, approximately 16 million Americans are estimated to have COPD, although the true prevalence of people with chronic airflow obstruction as measured by spirometry may exceed 28 million.[7] Despite a decline in the rate of cigarette smoking among adults in the United States, the prevalence of airflow obstruction and COPD is not expected to significantly decrease in the future. Approximately 14% of the population in the United States currently smoke cigarettes. While cessation of cigarette smoking has steadily decreased over the last 10 years, the use of e-cigarettes and smokeless tobacco products has increased.[8] Historically considered a disease primarily affecting White men, women in the United States are now more likely to have a diagnosis of COPD than men. The prevalence of COPD diagnosis also varies among ethnic and racial groups and by state or region of the country. Among ethnic and racial groups, American Indians/Alaskan Natives are more affected than others, and the prevalence is higher in some southeastern states.[9,10]

Chronic obstructive pulmonary disease is the fourth leading cause of death in the United States, exceeded only by cancer, heart disease, and unintentional injuries. Over 150,000 deaths are attributed to COPD annually.[9,10] In contrast to other leading causes of death, which have declining mortality rates, the mortality rate attributable to COPD has increased over the last 40 years. The trend of increasing COPD mortality likely reflects the long latency period between smoking exposure and complications associated with COPD. Between 1969 and 1985, the mortality rate due to COPD increased for men and then plateaued between 1985 and 1999.[11] From 1999 to 2014, the mortality rate due to COPD decreased among men but remained unchanged among women.[11,12] The magnitude difference is likely reflective of changes in smoking status among women in the first decades of the 20th century, although other gender-based differences may also contribute.[13]

While the mortality associated with COPD is significant, morbidity and costs associated with the disease also have a significant impact on patients, their families, and the healthcare system. Annually, patients with COPD account for over 15 million physician office visits and 700,000 hospitalizations. Surveys indicate that individuals with COPD are more likely to report physical activity limitations and be unable to work compared to individuals without COPD.[14] In the United States, an estimated $32 billion was spent on services related to COPD care in 2010 and increasing to $49 billion in the year 2020.[6] Costs associated with the disease are directly related to the severity of COPD and frequency of exacerbations.

ETIOLOGY

③ Cigarette smoking is the most common risk factor and accounts for approximately 75% of cases of COPD in the United States.[1,10] Although the remaining 25% of patients who develop COPD do not have a history of smoking, these patients may have exposure to environmental tobacco smoke or secondhand smoke through their occupation or family. Components of tobacco smoke activate inflammatory cells, which produce and release the inflammatory mediators characteristic of COPD. Smokers are 12 to 13 times more likely to die from COPD than nonsmokers.[15] Although the risk is lower in pipe and cigar smokers, it is still higher than in nonsmokers. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality.

Chronic obstructive pulmonary disease is attributed to a combination of risk factors that results in lung injury and tissue destruction, as evidenced by the fact that less than 50% of all smokers develop COPD, but not all smokers who have equivalent smoking histories develop the same degree of pulmonary impairment.[16] Risk factors can be divided into host factors and environmental factors (Table 45-1), and the interaction between these risks leads to the expression of the disease. Host factors, such as genetic predisposition, may not be modifiable but are important for identifying patients at high risk of developing the disease.

TABLE 45-1

Risk Factors for Development of Chronic Obstructive Pulmonary Disease (COPD)

Exposures	Host Factors
Environmental tobacco smoke	Genetic predisposition (AAT deficiency)
Occupational dust and chemicals	Airway hyperresponsiveness
Air pollution	Impaired lung growth

Environmental factors, such as tobacco smoke, occupational dust, and chemicals, are modifiable factors that, if avoided, may reduce the risk of disease development. Environmental exposures associated with COPD are particles that are inhaled by the individual, which result in inflammation and cell injury. Exposure to multiple environmental toxins increases the risk of COPD. Thus, the total burden of inhaled particles (eg, cigarette smoke as well as occupational and environmental particles and pollutants) plays a significant role in the development of COPD. It is helpful to assess an individual's total burden of inhaled particles. For example, an individual who smokes and works in a textile factory has a higher total burden of inhaled particles than an individual who smokes and has no occupational exposure.

In nonindustrialized countries, occupational exposures may be a more common risk than cigarette smoking. These exposures include dust and chemicals such as vapors, irritants, and fumes. Reduced lung function and deaths from COPD are higher for individuals who work in gold and coal mining, in the glass or ceramic industries with exposure to silica dust, and in jobs that expose them to cotton dust or grain dust, toluene diisocyanate, or asbestos. Other occupational risk factors include chronic exposure to open cooking or heating fires. It is unclear whether air pollution alone is a significant risk factor for the development of COPD in smokers and nonsmokers with normal lung function. However, in individuals with existing pulmonary dysfunction, significant air pollution worsens symptoms.

Individuals exposed to the same environmental risk factors do not have the same chance of developing COPD, suggesting that host factors play an important role in pathogenesis. Specific genes, such as matrix metalloproteinase 12 (MMP12), α_1-antitrypsin, and other genetic markers, have been implicated with the decline of lung function and potential risk of developing COPD.[1] However, only hereditary deficiency of α_1-antitrypsin (AAT) has been definitively shown to correlate with the development of emphysema and pulmonary dysfunction.[17] AAT-associated emphysema is an example of a purely genetic disorder inherited in an autosomal recessive pattern. A primary role of AAT, a plasma protein synthesized in hepatocytes, is to protect cells, especially those in the lung, from destruction by elastase released by neutrophils. Deficiency of AAT results in a protease–antiprotease imbalance and accelerated decline in lung function. Several types of AAT deficiency have been identified and are due to mutations in the AAT gene. True AAT deficiency accounts for less than 1% of COPD cases.[1]

Patients with AAT deficiency develop COPD at an early age (20-50 years) primarily owing to an accelerated decline in lung function. Compared with an average annual decline in forced expiratory volume in 1 second (FEV_1) of 25 mL/year in healthy nonsmokers, patients with homozygous AAT gene deficiency have been reported to have declines of 54 mL/year for nonsmokers and 108 mL/year for current smokers. Effective diagnosis is dependent on clinical suspicion, diagnostic testing of serum concentrations, and genotype confirmation.[17] Patients developing COPD at an early age or those with a strong family history of COPD should be screened for AAT deficiency.

Additional host factors that may influence the risk of developing COPD include airway hyperresponsiveness and lung growth. Individuals with airway hyperresponsiveness, such as asthma, to various inhaled particles may have an accelerated decline in lung function compared with those without airway hyperresponsiveness. Additionally, individuals who do not attain maximal lung growth owing to low-birth weight, prematurity at birth, or childhood illnesses may be at risk for COPD in the future.[1]

PATHOPHYSIOLOGY

Chronic obstructive pulmonary disease is characterized by chronic inflammatory changes that lead to destructive tissue changes and chronic airflow limitation. The inflammatory process is widespread and involves airways, pulmonary vasculature, and lung parenchyma. Exposure to noxious gas and particles activate inflammatory cells to release a variety of chemical mediators. While both asthma and COPD result from inflammatory responses, it is helpful to contrast the types of inflammatory cells and mediators involved because the response to anti-inflammatory therapy differs between the two diseases. The inflammation seen in COPD is often referred to as *neutrophilic* in nature, but macrophages and CD8+ lymphocytes also play major roles.[1,18] In a small subset of patients with COPD, there may be inflammation common to both COPD and asthma, and such patients may be classified as having “asthma-COPD overlap syndrome.”[19] Characteristics of inflammation for the two diseases are summarized in Table 45-2.

TABLE 45-2

Features of Inflammation in COPD Compared with Asthma

	COPD	Asthma
Cells	Neutrophils Large increase in macrophages Increase in CD8+ T lymphocytes	Eosinophils Small increase in macrophages Increase in CD4+ Th2 lymphocytes Activation of mast cells
Mediators	LTB4 IL-8 TNF-α	LTD4 IL-4, IL-5 (Plus many others)
Consequences	Squamous metaplasia of the epithelium Parenchymal destruction Mucus metaplasia Glandular enlargement	Fragile epithelium Thickening of basement membrane Mucus metaplasia Glandular enlargement
Response to treatment	Glucocorticosteroids have a variable effect	Glucocorticosteroids inhibit inflammation

Other processes proposed to play a major role in the pathogenesis of COPD include increased oxidative stress and imbalance between destructive and protective defense systems in the lungs (proteases and antiproteases).[1,20] Altered interaction between airway oxidants and antioxidants is responsible for the increased oxidative stress present in COPD. Increases in oxidant markers (eg, hydrogen peroxide and nitric oxide) are seen in the epithelial lining fluid and are generated by cigarette smoke or noxious particles.[1]

Oxidants react with and damage various proteins and lipids, leading to cell and tissue damage. Oxidants also promote inflammation directly and exacerbate the protease–antiprotease imbalance by inhibiting antiprotease activity.[20] These processes may be the result of ongoing inflammation or occur because of environmental pressures and exposures (Fig. 45-1).

Pathologic changes of COPD are widespread, affecting large and small airways, lung parenchyma, and the pulmonary vasculature.[1] An inflammatory exudate is often present that leads to an increase in the number and size of goblet cells and mucus glands. Mucous secretion is increased, and ciliary motility is impaired. There is also a thickening of smooth muscle and connective tissue in the airways. Inflammation is present in central and peripheral airways. The chronic inflammation results in a repeated injury and repair process that leads to scarring and fibrosis. Diffuse airway narrowing is present and is more prominent in smaller peripheral airways. Airflow obstruction is attributed to airway inflammation, while the blood gas abnormalities result from impaired gas transfer due to parenchymal damage and loss of alveolar-capillary networks.

Mucus hypersecretion is present early in the course of the disease and is associated with an increased number and size of mucus-producing cells. The presence of chronic inflammation perpetuates the process, although resulting airflow obstruction and chronic airflow limitation may be reversible or irreversible. The various causes of airflow obstruction are summarized in Table 45-3.

TABLE 45-3

Etiology of Airflow Limitation in COPD

Reversible
Presence of mucus and inflammatory cells and mediators in bronchial secretions
Bronchial smooth muscle contraction in peripheral and central airways
Dynamic hyperinflation during exercise
Irreversible
Fibrosis and narrowing of airways
Reduced elastic recoil with loss of alveolar surface area
Destruction of alveolar support with reduced patency of small airways

Parenchymal changes affect the gas-exchanging units of the lungs, including the alveoli and pulmonary capillaries. As the disease progresses, abnormalities in gas exchange lead to hypoxemia and/or hypercapnia, although there is not a strong correlation between pulmonary function and arterial blood gas (ABG). Significant changes in ABGs usually are not present until airflow limitation is very severe.[1] In such patients, hypoxemia, or low arterial oxygen tension (pressure exerted by oxygen gas in arterial blood [PaO_2] = 45-60 mm Hg [6.0-8.0 kPa]), and hypercapnia, or elevated arterial carbon dioxide tension (pressure exerted by carbon dioxide gas in arterial blood [$PaCO_2$] = 50-60 mm Hg [6.7-8.0 kPa]), can become chronic problems. Initially, when present, hypoxemia is associated with exertion. As the disease progresses, hypoxemia develops at rest. Hypoxemia is attributed to hypoventilation (V) of lung tissue relative to perfusion (Q) of the area. This low (V/Q) ratio will progress over a period of several years, resulting in a consistent decline in the PaO_2. Some COPD patients lose the ability to increase the rate or depth of respiration in response to persistent hypoxemia.

As COPD progresses and gas exchange worsens, patients may exhibit chronic hypercapnia and are referred to as carbon dioxide retainers. In such patients, central respiratory response to chronically increased $PaCO_2$ is blunted. These changes in PaO_2 and $PaCO_2$ are subtle and progress over a period of many years. As a result, serum pH usually is near normal because the kidneys compensate by retaining bicarbonate. If acute respiratory distress develops, such as seen with significant pneumonia or COPD exacerbation with respiratory failure, $PaCO_2$ may rise sharply, and the patient presents with a worsening respiratory acidosis.

The vascular changes of COPD include loss of pulmonary capillary beds, thickening of pulmonary vessels, and vasoconstriction of pulmonary arteries in response to hypoxemia.[1,21] Chronic hypoxemia and permanent changes in pulmonary vasculature lead to increases in pulmonary pressures, especially during exercise. When elevated pulmonary pressures are sustained, right-sided heart failure, or cor pulmonale, develops and is characterized by right ventricle hypertrophy in response to increased pulmonary vascular resistance. Pulmonary hypertension is the most common cardiovascular complication of COPD and can result in significant morbidity.

Thoracic over-inflation is a relevant feature in the pathophysiology of COPD because it is a central factor in causing dyspnea. Chronic airflow obstruction leads to air trapping, resulting in thoracic hyperinflation that can be detected on chest radiograph. Hyperinflation results in several dynamic changes in the chest, including flattening of diaphragmatic muscles. Under normal circumstances, diaphragms are dome-shaped muscles tethered at the lung bases. When diaphragms contract, the muscles become shorter and flatter, creating the negative inspiratory force through which air flows into lungs during inspiration. With thoracic hyperinflation, diaphragmatic muscles are placed at a disadvantage and are less efficient muscles of ventilation. Increased work required by diaphragmatic contractions predisposes patients to muscle fatigue, especially during periods of exacerbations.

Another consequence of thoracic hyperinflation is the change in lung volumes. For patients with COPD exhibiting thoracic hyperinflation, there is an increase in functional residual capacity (FRC), which is the amount of air left in the lung after exhalation at rest. Therefore, these patients are breathing at higher lung volumes that perturb gas exchange. Increased FRC limits the inspiratory reserve capacity, which is the amount of air that the patient can inhale to fill the lungs. Increased FRC limits the duration of inhalation time and has been associated with increased complaints of dyspnea by patients.[1] Pharmacotherapy for COPD, especially bronchodilators, can reduce thoracic hyperinflation by reducing airflow obstruction and air trapping. This explains symptom improvement reported by patients with COPD despite minimal improvements in expiratory lung function.

Another important systemic consequence of COPD is loss of skeletal muscle mass and a general decline in the overall health status. These changes are partially attributed to systemic inflammation and can have devastating effects on overall health status and comorbidities. Systemic effects include cardiovascular events associated with ischemia, cachexia, weight loss, osteoporosis, anemia, and muscle wasting.[1] There has been interest in measuring C-reactive protein as a marker to assess systemic inflammation and its correlation with disease severity; however, it is premature to recommend its use in practice for chronic management.[22] Instead, C-reactive protein may have a role in identifying patients with acute exacerbation of COPD who should receive treatment with antibiotics.

CLINICAL PRESENTATION: Chronic Obstructive Pulmonary Disease

Symptoms

- Chronic cough—may be intermittent; may be unproductive
- Chronic sputum production
- Dyspnea—worse with exercise; progressive over time
  - Decreased exercise tolerance or decline in physical activity
  - Chest tightness or wheezing

Risk Factors

- Tobacco smoke exposure
- Indoor air pollution (eg, burning wood and biofuel for cooking or heating)
- Occupational and environmental hazards (eg, organic and inorganic dusts, chemical fumes)
- α_1-Antitrypsin deficiency

Physical Examination

- Shallow breathing
- Increased resting respiratory rate
- Pursed lips during exhalation
- Use of accessory respiratory muscles
- Cyanosis of mucosal membranes (seen in later stages of disease)

Diagnostic Tests

- Spirometry with postbronchodilator testing
- Radiograph of chest (to rule out other diagnoses)
- Arterial blood gas (not routinely obtained in chronic management; has utility in acute decompensation). Lab abnormalities may include pH <7.35, PaO_2 <80 mm Hg (10.6 kPa), $PaCO_2$ >50 mm Hg (6.7 kPa), and bicarbonate >26 mEq/L (mmol/L)

The diagnosis of COPD is made based on the patient's symptoms, history of exposure to risk factors, and confirmed by pulmonary function testing, such as spirometry. Patients may experience cough for several years before dyspnea develops and often will not seek medical attention until dyspnea is significant. A diagnosis of COPD should be considered for any patient, age 40 years or older, with persistent or progressive dyspnea, with chronic cough productive of sputum, and who exhibits an unusual or abnormal decline in activity, especially in the presence of exposure to environmental tobacco smoke. In addition, the presence of genetic factors, including AAT deficiency, and occupational exposures should be evaluated as approximately 15% of patients with COPD do not have a history of cigarette smoking. Current preventative guidelines do not endorse routine screening tests for asymptomatic patients with risk factors for COPD, although some medical societies advocate proactively identifying patients early in the stages of the disease.[23]

Spirometry combined with physical examination improves the diagnostic accuracy of COPD.[1] Spirometry represents a comprehensive assessment of lung volumes and capacities. Patients with all levels of severity of COPD exhibit the hallmark finding of airflow obstruction; specifically, a reduction in FEV_1/FVC ratio to less than 70% (0.70). FVC is the total volume of air exhaled after maximal inhalation and FEV_1 is the total volume of air exhaled in 1 second. A fixed ratio of less than 70% (0.70) may be problematic because normal aging may affect this result; however, it continues to be the current standard. Previous criteria for the diagnosis of COPD included measuring the degree of airflow limitation before and after inhaled bronchodilator challenge. It is no longer recommended to obtain prebronchodilator values or to calculate the degree of reversibility to diagnose COPD (Table 45-4).[1] Postbronchodilator spirometry results should be used in assessing lung function in patients with COPD.

TABLE 45-4

Procedures for Postbronchodilator Testing

Preparation Tests should be performed when patients are clinically stable and free from a respiratory infection. Patient must be able to participate with maximal effort during the test
Spirometry Bronchodilators can be given by either a metered-dose inhaler or nebulization Usual doses are 400 mcg of β-agonist, 160 mcg of anticholinergic, or the two combined FEV_1 should be measured 10-15 minutes after a short-acting β-agonist or 30-45 minutes after a short-acting anticholinergic or combination
Results Airflow limitation is confirmed by a postbronchodilator FEV_1/FVC <0.70

Data from Reference 1.

Spirometry is useful to confirm the presence of airflow limitation and to determine the severity of obstruction.[24] GOLD consensus guidelines suggest a four-grade classification of airflow limitation (Table 45-5). The use of peak expiratory flow measurements as a diagnostic tool or to classify severity is not adequate for COPD due to low specificity and the high degree of effort dependence; however, a low peak expiratory flow is consistent with the clinical presentation of COPD. A comprehensive discussion about spirometry and interpretation can be found in Chapter e43, "Evaluation of Respiratory Function."

TABLE 45-5

Spirometric Grades: Classification of Severity of Airflow Obstruction (Based on Postbronchodilator FEV_1)

GOLD 1: mild $FEV_1/FVC < 70\%$ (0.70) $FEV_1 \geq 80\%$ With or without symptoms
GOLD 2: moderate $FEV_1/FVC < 70\%$ (0.70) $50\% \leq FEV_1 < 80\%$ With or without symptoms
GOLD 3: severe $FEV_1/FVC < 70\%$ (0.70) 30% ≤ FEV1 <50% With or without symptoms
GOLD 4: very severe $FEV_1/FVC < 70\%$ (0.70) $FEV_1 < 30\%$

Data from Reference 1.

Dyspnea is typically the most troublesome complaint for patients with COPD and often is the stimulus for seeking medical attention. It can impair exercise performance and functional capacity and is frequently associated with depression and anxiety. Together, these have a significant effect on health-related quality of life.[1] As a subjective symptom, dyspnea is often difficult for the clinician to assess. Various tools are available to evaluate the severity of dyspnea. The modified Medical Research Council (mMRC) scale is commonly employed and categorizes dyspnea grades from 0 to 4.[1] Patients with COPD may experience a variety of symptoms, not limited only to dyspnea. Therefore, the impact of COPD on other measures of health status has been recognized and newer patient assessment tools, such as COPD assessment Test (CAT) and COPD Control Questionnaire (CCQ), include items related to overall symptoms and activities. Other patient assessment questionnaires, such as the Chronic Respiratory Questionnaire (CRQ) and St. George's Respiratory Questionnaire (SGRQ), are comprehensive measures of disease impact on health status and are used frequently in clinical trials; however, use in clinical practice is limited by their length and complexity. There are three patient assessment questionnaires amenable to use in routine clinical practice and recommended by international guidelines (Table 45-6).[1]

TABLE 45-6

Comparison of Patient Assessment Questionnaires Used in COPD

Name	Description of Scoring System	Link to Assessment Tool
COPD Assessment Test (CAT)	• Includes 8 items related to health status and impact of COPD on daily activities • Each item scored 0-5 with a maximum total score of 40 • Score of <10 means less symptoms • Score of ≥10 means more symptoms	http://catestonline.org
Modified Medical Research Council Dyspnea Questionnaire (mMRC)	• Includes 5 descriptive statements related to dyspnea only • Patient chooses the most appropriate statement • Each statement corresponds to a score of 0-4 • Score of <2 means less symptoms • Score of ≥2 means more symptoms	http://www.goldcopd.org
COPD Control Questionnaire (CCQ)	• Includes 10 items in 3 domains related to symptoms, functional state, mental state • Assesses clinical control of disease in the past week • Score weighted for each domain • Score <1 means less symptoms[a] • Score ≥1 means more symptoms[a]	http://www.ccq.nl

[a] Exact cut point values have not yet been established for this assessment questionnaire.

Classification Based on Severity

4 Previously, therapy guidelines have defined disease severity solely by spirometry. Observations that patients with similar spirometric parameters exhibit variations in symptom severity and risk of adverse health events, such as exacerbations, led to a revision in severity classification. The GOLD consensus guidelines recommend using multiple factors to determine disease severity, and that spirometric severity (ie, GOLD spirometric grade 1-4, see Table 45-5) be evaluated separately from symptom and exacerbation risk. A combined "ABCD" classification system is now used and the classification is based on the patient's symptom severity and risk of future exacerbation (Table 45-7). This classification system acknowledges that symptom management and prevention of exacerbations should be used to guide therapy. Classification of airflow limitation severity and spirometric grade predicts disease outcomes such as mortality and exacerbations and is useful when considering therapies such as lung reduction surgery or transplantation.

TABLE 45-7

Combined Assessment of COPD Severity

Patient Group	Description	Exacerbations in Last Year[a]	CAT	mMRC
A	Less symptoms; low risk	0-1	<10	0-1
B	More symptoms; low risk	0-1	≥10	≥2
C	Less symptoms; high risk	≥2	<10	0-1
D	More symptoms; high risk	≥2	≥10	≥2

[a] > exacerbation, or one requiring hospitalization equals high risk (eg, Patient Group C or D)

Data from Reference 1.

Symptom assessment should be measured at baseline and then during routine visits using CAT or mMRC. Defined cut points for patients exhibiting "more symptoms" and "less symptoms" have been established for CAT and mMRC but are not as well defined for CCQ. The frequency of exacerbations can be assessed by a review of exacerbation history for the past 12 months. Patients with at least two exacerbations in the last 12 months, or one exacerbation requiring hospitalization, are considered high risk for future exacerbations (category C or D). Patients are then assigned to an ABCD category based on these two assessments. Classifying patients according to ABCD categories helps inform treatment decisions as guideline-recommended initial and escalation therapy is based on ABCD category classification.

Prognosis

Patients with COPD are a heterogeneous group and multiple factors, such as airflow limitation, age, frequency and severity of exacerbations, and comorbidities, have been implicated in the rate of disease progression and prognosis. The rate of COPD progression is variable and not easily predicted for individual patients. Several prognostic indices have been shown to be useful in predicting survival among populations of patients with COPD (Table 45-8).[25,26] Based on prognostic indices, mortality for patients with COPD increases with worsening airflow limitation (lower FEV_1 percent of predicted), greater age, lower body mass index (BMI), higher dyspnea score (mMRC), shorter 6-minute walk distance, continued smoking, frequent and severe exacerbations, and presence of selected comorbidities. The primary causes of death of patients with COPD include respiratory failure, cardiovascular events or diseases, and lung cancer.[1] Advanced directives, palliative care coordination and end-of-life care are appropriate options to consider for patients with significant progression and comorbidities.

TABLE 45-8

Selected Prognostic Indices Used in COPD

Name	Description of Tool
BMI, Obstruction, Dyspnea, Exercise (BODE) Index	• Composite score of body mass index, measured FEV1, mMRC score, and 6MWT distance • Score provides an estimate of 4-year survival • Well-known and validated tool
Age, Dyspnea, Obstruction (ADO) Index	• Composite score of age, mMRC score, and measured FEV1 • Score provides an estimate for 3-year survival • Maybe more helpful in primary care if 6MWT cannot be measured
COPD Specific Comorbidity Test (COTE) Index	• Includes 12 comorbidities observed to contribute to mortality in COPD patients • Better predictive power if combined with ADO or BODE index

FEV_1, forced expiratory volume in one second; mMRC, modified Medical Research Council scale; 6MW, six-minute walk test

Complications of Progressive COPD

Pulmonary Hypertension

Pulmonary hypertension associated with COPD (PH-COPD) may occur in up to 30% of patients and is associated with increased mortality.[27] Given the management complexity of patients with pulmonary hypertension, referral to expert centers specializing in PH is recommended. Investigations of pharmacologic therapy typically used in the treatment of pulmonary arterial hypertension (ie, endothelin receptor antagonists, phosphodiesterase type 5 (PDE5) inhibitors, prostacyclin analogs) for patients with PH-COPD are limited and provide conflicting results. Due to concerns of worsening gas exchange in patients with COPD, pulmonary vasodilators are not recommended outside of clinical trials or specialized pulmonary hypertension centers.

Cor Pulmonale

Cor pulmonale is right-sided heart failure secondary to pulmonary hypertension. Long-term oxygen therapy and diuretics are mainstays of therapy for cor pulmonale. Increasing PaO_2 above 60 mm Hg (8.0 kPa) with supplemental oxygen therapy decreases pulmonary hypertension and resistance against which the right ventricle must work. While diuretics may help decrease fluid overload, caution should be used because patients with significant right-sided heart failure are highly dependent on preload for cardiac output. Digitalis glycosides have no role in the treatment of cor pulmonale.

Beta-blocker therapy is indicated to treat systolic heart failure including patients who have experienced a myocardial infarction. Beta-blocker therapy can present unique challenges for patients with airway disease but are generally well tolerated by patients with COPD who do not exhibit bronchial hyperreactivity. Patients with COPD should generally be treated with β_1-selective agents, although there is some evidence the non-seletive agents can be tolerated. Use of beta-blocker therapy for patients with COPD and cardiac disease has been associated with improved overall survival.[28]

Polycythemia

Polycythemia secondary to chronic hypoxemia in COPD patients can be improved by either continuous oxygen therapy (COT) or periodic phlebotomy if oxygen therapy alone is not sufficient. Acute phlebotomy is indicated if the hematocrit is above 55% to 60% (0.55-0.60) and the patient is experiencing CNS effects suggestive of sludging from high blood viscosity. Long-term oxygen then can be used to maintain a lower hematocrit.

TREATMENT

Chronic Obstructive Pulmonary Disease

Desired Outcome

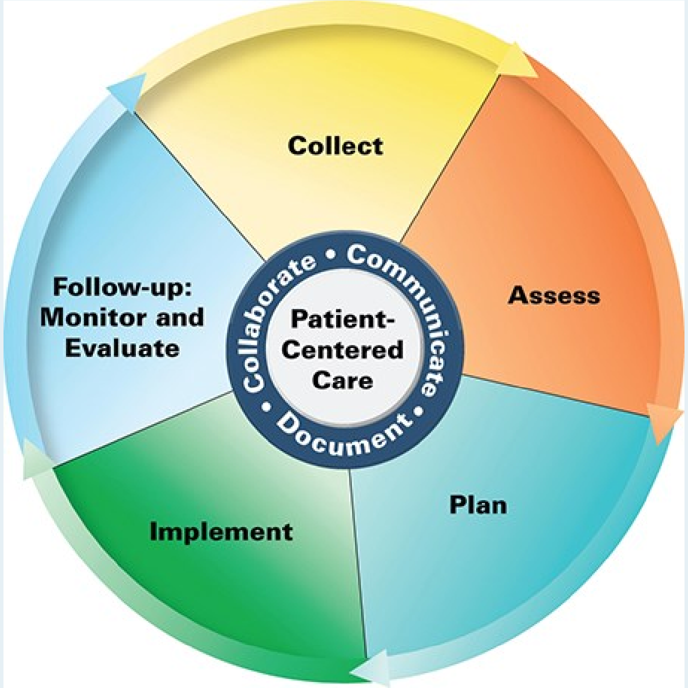
Given the significant clinical and economic impact of COPD, a major focus in healthcare should be on its prevention in patients at risk of the disease. Limiting or eliminating exposure to tobacco smoke and other environmental irritants should be the goal of prevention efforts. For patients already with a diagnosis of COPD, the primary goal is to prevent or slow disease progression. Specific goals are listed in Table 45-9. Optimally, these goals can be accomplished with minimal risks or adverse effects. Therapy of the patient with COPD is multifaceted and includes pharmacologic and nonpharmacologic strategies.

TABLE 45-9

Goals of COPD Management

1. Prevent disease progression
2. Relieve symptoms
3. Improve exercise tolerance
4. Improve overall health status
5. Prevent and treat exacerbations
6. Prevent and treat complications
7. Reduce morbidity and mortality

Patient Care Process for the Management of Chronic Obstructive Pulmonary Disease (COPD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

The image shows the five fundamental steps included in patient care process for nausea and vomiting. The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, gender)
- History of present illness including a history of COPD exacerbations in last 12 months and management (eg, home, Primary Care Provider visit, Emergency Department visit, or hospitalization)
- Patient history (past medical, family, social-environmental exposures, tobacco use, exercise tolerance, and capacity)
- Current medications including immunizations (eg, influenza, pneumococcus, tetanus/diphtheria/pertussis) and any prior pulmonary medication use
- Objective data (see Tables 45-5 to 45-7)
  - Symptom scores using validated questionnaire (eg, CAT, mMRC)
  - Current and previous spirometry/pulmonary function tests (eg, FEV_1)

Assess

- Severity of symptoms (eg, “more symptoms” or “less symptoms” based on questionnaires, Table 45-6)
- Risk of future exacerbation (eg, high risk or low risk)
- Degree of airflow limitation (eg, GOLD spirometry group, Table 45-5)
- Patient category based on GOLD Combined Assessment (eg, Category ABCD, Table 45-7)
- Readiness to quit, if current tobacco use (see Tables 45-10 to 45-12)
- Appropriateness and effectiveness of current pulmonary medication regimen
- Ability to administer/participate with inhaled therapies (eg, dexterity, vision, coordination)
- Ability to pay for medications (eg, insurance, formulary considerations, self-pay)

Plan

- Patient-specific goals of therapy (see Tables 45-13 and 45-19)
- Preventative health measures (e.g. immunizations, smoking cessation)
- Drug therapy regimen including specific medication, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Tables 45-13 and 45-14)
- Oxygen therapy if severe airflow limitation
- Monitoring parameters including efficacy (eg, symptoms, exacerbations), safety (medication-specific adverse effects), and time frame
- Patient education (eg, purpose of medications, administration technique, recognition of exacerbations)
- Referrals to other providers when appropriate (eg, physician, pulmonary rehabilitation)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence

- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Determine goal attainment (eg, symptoms, exacerbations, complications)
- Presence of treatment-related adverse effects
- Patient adherence to treatment plan using multiple sources of information

Collaborate with patient, caregivers, and other healthcare professionals.

Unfortunately, most treatments for COPD have not been shown to improve survival or to slow the progressive decline in lung function. However, many therapies do improve pulmonary function and quality of life as well as reduce the risk of COPD exacerbations and duration of hospitalization. While earlier studies of COPD therapies focused primarily on relief of symptoms and improvements in pulmonary function measurements such as FEV_1, more recent studies also measure disease-specific quality-of-life and the frequency and severity of exacerbations. A reduction in exacerbation frequency is an important outcome to consider when evaluating the role and benefit of chronic therapies used in COPD management.

General Approach to Treatment

To be effective, clinicians should address four major components of management: assess and monitor the condition, avoid or reduce exposure to risk factors, manage stable disease, and treat exacerbations.[1] These components are addressed through a variety of nonpharmacologic and pharmacologic approaches.

Nonpharmacologic Therapy and Health Maintenance Strategies

Patients with COPD should receive education about their disease, treatment plans, and strategies to slow progression and prevent complications. For those patients who smoke and who are exposed to environmental smoke, advising and counseling patients about smoking cessation are essential for patients in all stages of the disease. Because the natural course of the disease leads to respiratory failure, clinicians should address end-of-life decisions and advanced directives prospectively with the patient and family. Increasingly, palliative care services, which include both end-of-life and hospice care for patients with all types of life-threatening acute and chronic illnesses, have been utilized for patients with severe COPD.[29]

Smoking Cessation

⑤ Smoking cessation represents the single most important intervention in preventing the development, as well as progression, of COPD. A primary component of COPD management is avoidance of or reduced exposure to risk factors. Smoking cessation leads to decreased symptomatology and slows the rate of decline of pulmonary function even after significant abnormalities in pulmonary function tests have been detected. As confirmed by the Lung Health Study, smoking cessation is the only intervention proven to affect long-term decline in FEV_1 and slow the progression of COPD.[30] In this 5-year prospective trial, smokers with early COPD were randomly assigned to one of three groups: smoking-cessation intervention plus inhaled ipratropium three times a day, smoking-cessation intervention alone, or no intervention. During an 11-year follow-up, the rate of decline in FEV_1 among subjects who continued to smoke was more than twice the rate in sustained quitters.[31] Smokers who underwent smoking-cessation intervention had fewer respiratory symptoms and a smaller annual decline in FEV_1 compared with smokers who had no intervention.

Tobacco cessation has mortality benefits beyond those related to COPD. A follow-up analysis of the Lung Health Study data conducted more than 14 years later demonstrated an 18% reduction in all-cause mortality in patients who received the intervention compared with usual care.[32] Intervention patients had lower death rates due to cardiovascular diseases (the leading cause of mortality) and lung cancer.

Every clinician has a responsibility to advise smokers regarding smoking cessation and should take an active role in assisting patients with tobacco dependence to reduce the burden on the individual, their family, and the healthcare system. Counseling that is provided by clinicians is associated with greater success rates than self-initiated efforts. The major findings from recent clinical practice guidelines for treating tobacco dependence are summarized in Table 45-10. Since 2004, reports from the Surgeon General on the health consequences of smoking have emphasized the detrimental effects of cigarette smoking on the general health of smokers and individuals exposed to secondhand smoke. Over 20 million Americans have died prematurely from exposure to cigarette smoking since 1964.

TABLE 45-10

Key Guideline Recommendations Regarding Tobacco Use and Dependence

- Tobacco dependence is a chronic disease that often requires repeated intervention and multiple attempts to quit. Effective treatments are available that can significantly improve rates of long-term abstinence
- Clinicians and healthcare delivery systems should systemically identify tobacco use and dependence and treat every patient who uses tobacco
- Tobacco-dependence treatments are effective over a broad range of populations. Clinicians should encourage every patient willing to quit to use counseling and medications recommended in the guideline
- Brief tobacco-dependence treatments are effective. Clinicians should offer every patient who uses tobacco at least these brief treatments
- Individual, group, and telephone counseling are effective, and their effectiveness increases with treatment intensity. Practical counseling (problem-solving and/or skills training) and social support are very effective and should be part of treatment
- There are numerous effective medications for tobacco dependence, and clinicians should encourage their use by patients during a quit attempt, except when medically contraindicated or with populations in which the evidence of effectiveness is insufficient (pregnancy). Seven first-line medications (5 nicotine and 2 non-nicotine) consistently increase long-term abstinence rates. Clinicians should also consider the use of combinations as identified in the guideline
- Counseling and medication are effective when used by themselves for treating tobacco dependence. The combination of the two is more effective than either alone. Patients should be encouraged to use both counseling and medication
- Telephone quitline counseling is effective for diverse populations and offers the advantage of broad reach. Clinicians should ensure patient access to quitlines and promote quitline use
- For a patient with tobacco dependence who is currently unwilling to make a quit attempt, clinicians should use motivational treatments that have been shown to be effective in increasing future quit attempts
- Tobacco-dependence treatments are both clinically effective and highly cost-effective relative to interventions for other clinical disorders. Providing coverage for these treatments increases quit rates. Insurers and purchasers should ensure that all insurance plans include the counseling and medications identified as effective in the guideline as covered benefits

Data from References 33 and 34.

Evidence from long-term trials shows that tobacco cessation, either sustained or intermittent, is of benefit at any point. For patients with COPD, maximum benefit is seen with early and sustained cessation; however, incremental benefit is seen at all time points. Given that approximately 40% of patients with COPD continue to smoke, patients and clinicians should understand it is never too late to quit, and repeated attempts at cessation may be necessary. Approximately 70% of smokers want to quit, and over half have made a cessation attempt in the last year. Yet complete and sustained tobacco cessation is difficult.[33,34] Understanding that tobacco dependence is a chronic disease, the focus should be on congratulating and encouraging patients for any behavior changes that result in reduced exposure to tobacco smoke rather than admonishing patients for unsuccessful attempts, relapses, or incomplete cessation.

The guidelines recommend that clinicians take a comprehensive approach to smoking cessation assessment. All patients should be routinely assessed for tobacco use and advice given to smokers even if they have no symptoms of smoking-related disease or if they are receiving care for reasons unrelated to smoking. Clinicians should be persistent in their motivational efforts to determine the patient’s readiness and support cessation attempts. Even brief interventions (3 minutes) of counseling have been shown to be effective. There are several stages that influence patient decision-making. Based on this, a five-step intervention program is proposed (Table 45-11).

TABLE 45-11

Five-Step Strategy for Smoking-Cessation Program (5 A’s)

Ask	Use a systematic approach to identify all patients who use tobacco at every visit
Advise	Strongly urge all patients who use tobacco to quit
Assess	Determine willingness and motivation to make a cessation attempt
Assist	Provide support for the patient to quit smoking
Arrange	Schedule follow-up and monitor for continued abstinence

There is strong evidence to support the use of pharmacotherapy to assist in smoking cessation, and therapy should be offered to most patients as part of a cessation attempt. In general, available pharmacotherapies will double the effectiveness of a cessation effort when combined with behavioral counseling. Agents considered first line are listed in Table 45-12. The usual duration of therapy is 8 to 12 weeks, although some individuals may require longer courses of treatment. Precautions to consider before using bupropion include a history of seizures or an eating disorder. Nicotine replacement therapies are contraindicated for patients with recent (less than 2 weeks) myocardial infarction or stroke. Varenicline, a nicotine acetylcholine receptor partial agonist, relieves physical withdrawal symptoms and reduces the rewarding properties of nicotine. Nausea and headache are the most frequent complaints associated with varenicline. Second-line agents are less effective or associated with greater adverse effects; however, they may be useful in selected clinical situations. These therapies include clonidine and nortriptyline, a tricyclic antidepressant. Given the significant increase in the use of e-cigarettes and other electronic nicotine delivery systems (ENDS), there is interest in the potential role of these nicotine delivery systems as smoking cessation strategies. It is not clear if substituting ENDS for traditional cessation therapy produces similar or greater tobacco cessation rates, and long-term safety outcomes of these systems have not been determined.[1,34] ENDS should not be recommended as part of a smoking cessation strategy until additional evidence is available. A comprehensive discussion of tobacco cessation can be found in Chapter 86, "Substance Use Disorders II: Alcohol Nicotine and Caffeine."

TABLE 45-12

First-Line Pharmacotherapies for Smoking Cessation

Agent	Usual Dose	Duration	Common Complaints
Bupropion SR	150 mg orally daily for 3 days, then twice daily	12 weeks, up to 6 months	Insomnia, dry mouth
Nicotine gum	2-4 mg gum prn, up to 24 pieces daily	12 weeks	Sore mouth, dyspepsia
Nicotine inhaler	6-16 cartridges daily	Up to 6 months	Sore mouth and throat
Nicotine nasal spray	8-40 doses daily	3-6 months	Nasal irritation
Nicotine patches	Various, 7-21 mg every 24 hr	Up to 8 weeks	Skin reaction, insomnia
Varenicline	0.5 mg daily orally for 3 days, then 0.5 mg twice daily for 4 days, then 1 mg twice daily	12 weeks	Nausea, sleep disturbances

Other Environmental Triggers

Although cigarette smoke is by far the most common risk for developing COPD in most patients, exposure to other environmental toxins also confers risks.[1] Exposure to occupational dust and fumes has been implicated as a cause of COPD in 19% of smokers and 31% of nonsmokers with COPD in the United States. In the case of known environmental hazards, primary prevention is appropriate. Policies to limit airborne exposures in the workplace and outdoors, as well as education efforts of workers and policymakers, are recommended.

Pulmonary Rehabilitation

Exercise training is beneficial in the treatment of COPD to improve exercise tolerance and to reduce symptoms of dyspnea and fatigue.[1] Pulmonary rehabilitation programs are an integral component in the management of COPD and should include exercise training along with smoking cessation, breathing exercises, optimal medical treatment, psychosocial support, and health education. Pulmonary rehabilitation has no direct effect on lung function or gas exchange. Instead, it optimizes other body systems so that the impact of poor lung function is minimized. Exercise training reduces the CNS response to dyspnea, ameliorates anxiety and depression, reduces thoracic hyperinflation, and improves skeletal muscle function.[35]

High-intensity training (70% maximal workload) is possible even in advanced COPD patients, and level of intensity improves peripheral muscle and ventilatory function. Studies have demonstrated that pulmonary rehabilitation with exercise three to seven times per week can produce long-term improvement in activities of daily living, quality of life, exercise tolerance, and dyspnea for patients with moderate-to-severe COPD.[36] Improvements in dyspnea do not always result in improvements in spirometry. While rehabilitation programs vary in length as well as exercise frequency and intensity, optimal benefits result from programs of 6 to 8 weeks in duration and including at least twice a week supervised sessions with targeted feedback.[1]

Surgical Intervention

Various surgical options have been employed in the management of COPD.[1] These include bullectomy, lung volume reduction surgery (LVRS), and lung transplantation. Presence of bullae may contribute to complaints of dyspnea, and their removal can improve lung function and reduce symptoms, although there is no evidence of a mortality benefit. Lung volume reduction surgery removes sections of lung to reduce hyperinflation and may improve survival in selected patients. Lung transplantation, either single or double, may improve exercise capacity and health status but median survival is only 5.5 years after transplant.[1]

Long-Term Oxygen Therapy

⑥ The use of supplemental oxygen therapy increases survival in COPD patients with chronic hypoxemia at rest. Patients receiving oxygen therapy for at least part of the day have lower rates of mortality than those not receiving oxygen. Long-term oxygen therapy provides more benefit in terms of survival after at least 5 years of use and improves the quality of life for patients by increasing walking distance, improving neuropsychological condition, and reducing time spent in the hospital.[1] Before patients are considered for long-term oxygen therapy, they should be stabilized in the outpatient setting, and pharmacotherapy should be optimized. Once optimized, long-term oxygen therapy should be instituted if either of the following conditions are observed and documented twice in a 3-week period:

1. A resting PaO_2 of less than 55 mm Hg (7.3 kPa) or SaO_2 less than 88% (0.88) with or without hypercapnia.
2. A resting PaO_2 between 55 and 60 mm Hg (7.3 and 8.0 kPa) or SaO_2 less than 88% (0.88) with evidence of right-sided heart failure, polycythemia, or pulmonary hypertension.

The most practical means of administering long-term oxygen is with a nasal cannula, at 1 to 2 L/min, providing 24% to 28% (0.24 to 0.28) fraction of inspired oxygen (FiO_2) with a goal to raise PaO_2 above 60 mm Hg (8.0 kPa). There are three different ways to deliver oxygen, including (a) in liquid reservoirs, (b) compressed into a cylinder, and (c) via an oxygen concentrator. Although conventional liquid oxygen and compressed oxygen are quite bulky, smaller, portable tanks are available to permit greater patient mobility. Oxygen concentrator devices separate nitrogen from room air and concentrate oxygen. These are the most convenient and the least expensive method of oxygen delivery. Oxygen-conservation devices are available that allow oxygen to flow only during inspiration, making the supply last longer. These may be particularly useful to prolong the oxygen supply for mobile patients using portable cylinders. However, devices are bulky and subject to failure. Patient education about flow rates and avoidance of flames (ie, smoking) is of the utmost importance.

Adjunctive Therapies

In addition to supplemental oxygen, adjunctive therapies to consider as part of a pulmonary rehabilitation program are psychoeducational care and nutritional support. Psychoeducational care (such as relaxation) has been associated with improvement in the functioning and well-being of adults with COPD.[1] The role of nutritional support for patients with COPD is controversial. Several studies have shown associations of malnutrition, low BMI, and impaired pulmonary status among patients with COPD. However, results from multiple studies suggest that the effect of nutritional support on physical and functional outcomes in COPD is small and may be most beneficial for malnourished patients.[37]

Vaccinations

The GOLD guidelines include specific recommendations about vaccines.[1] The CDC also provides advice about vaccines for COPD patients in the United States and these are updated periodically based on new evidence and as new vaccines become available. Recommended vaccines can reduce the likelihood of respiratory infections that lead to COPD exacerbations. Influenza is a common complication in COPD that can lead to exacerbations and respiratory failure. Therefore, annual vaccination with the inactivated intramuscular influenza vaccine is recommended.[1,38] Immunization against influenza can reduce exacerbations, hospitalization, all-cause death, and respiratory death in COPD patients.[39] Influenza vaccine should be administered annually during each influenza season. Vaccination against influenza can begin as early as August, with most patients being vaccinated during regular medical visits or at vaccination clinics in October and November. The oral antiviral agent, oseltamivir, can be considered for non-immunized patients with COPD during an outbreak; however, this therapy is less effective and causes more adverse effects.

Vaccination against pneumococcal infection is recommended for all adults with COPD. For individuals who have not previously received a pneumococcal conjugate vaccine (PCV), either PCV20 or PCV15 followed by a pneumococcal polysaccharide vaccine (PPSV23) at least one year later is recommended.[38] If the patient has previously received PPSV23, either PCV15 or PCV20 should be administered at least one year later. Individuals with COPD who have not received the tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine, the CDC and GOLD guidelines recommend Tdap and then subsequent tetanus and diphtheria boosters, with or without acellular pertussis, every 10 years.[1,40] Herpes zoster vaccine is recommended for adults with COPD at age 50 or older.[1]

After the global outbreak of novel coronavirus SARS-Co-V-2, the CDC recommend all individuals over the age of 5 years receive a viral vector or mRNA vaccine to prevent severe illness and death associated with coronavirus infection and disease (COVID-19).

Pharmacologic Therapy

In contrast to survival benefit conferred by supplemental oxygen therapy and tobacco cessation, there is no medication available for the treatment of COPD that has been conclusively shown to modify lung function decline or prolong survival.[1] There is some evidence that chronic treatment with pharmacotherapy may reduce the rate of lung function decline in a subset of patients, although more definitive studies are needed to confirm these observations. The primary goal of pharmacotherapy is to improve patient symptoms, reduce the frequency and severity of exacerbations, and improve the patient's exercise tolerance.

Currently available therapies for COPD are summarized in Tables 45-13, 45-14, and 45-15. International guidelines recommend a stepwise approach to the use of pharmacotherapy based on disease severity determined by an assessment of symptom burden and exacerbation risk.[1] The impact of recurrent exacerbations on accelerating disease progression is increasingly recognized as an important factor to be considered. There is inadequate evidence to support the routine use of more aggressive pharmacotherapy early in the course of the disease because of the lack of a disease-modifying benefit. Due to the progressive nature of COPD, pharmacotherapy tends to be chronic and cumulative. Step-down approaches in stable patients may be considered if adverse effects outweigh therapeutic benefits or if patients do not demonstrate a sufficient response. Patients exhibit varied responses to available therapies and the treatment approach must be individualized.

TABLE 45-13

Recommended Initial Pharmacologic Therapy for Stable COPD and Evaluation of Therapeutic Outcomes

Patient Group	Initial Therapy	Assessment

A (less symptoms, less risk)	Offer bronchodilator, either short- or long-acting depending on symptoms	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)
B (more symptoms, less risk)	Start either LAMA or LABA for symptom control	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)
C (less symptoms, more risk)	• Start long-acting bronchodilator for exacerbation prevention • LAMA is preferred over LABA for initial monotherapy	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)
D (more symptoms, more risk)	• LAMA is preferred over LABA for initial monotherapy • For severe breathlessness, may start with dual LAMA/LABA If less symptoms, may start only LAMA monotherapy and add LABA at a later time • If blood eosinophils ≥ 300 cells/microliter (0.3 x 10^9/L), start ICS/LABA as initial dual therapy	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)

CAT, COPD assessment test; ICS, inhaled corticosteroids; LABA, long-acting beta-agonist; LAMA, long-acting muscarinic antagonists; mMRC, modified Medical Respiratory Council questionnaire; SABA, short-acting beta-agonist; SAMA, short-acting muscarinic antagonists.

TABLE 45-14

Recommended Escalation Pharmacologic Therapy for Stable COPD and Evaluation of Therapeutic Outcomes

Target Symptom	Current Therapy	Assessment	Escalation Therapy
Dyspnea	LABA or LAMA monotherapy	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal) Assess other causes of dyspnea	Add additional long-acting bronchodilator if persistent symptoms on monotherapy. New regimen = LAMA + LABA If dual bronchodilators do not improve symptoms, consider changing device or active ingredient and/or stepping back to monotherapy If a patient becomes high risk for future exacerbations, choose escalation therapy based on the target symptom of “Exacerbations”
Dyspnea	LABA + ICS	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)	Add additional long-acting bronchodilator if persistent symptoms on dual therapy. New regimen = LAMA + LABA + ICS If pneumonia, inappropriate indication or lack of response to ICS, consider de-escalation back to LABA + LAMA only
Exacerbations	LABA or LAMA monotherapy	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)	Add long-acting bronchodilator if persistent exacerbations on monotherapy. New regimen = LABA + LAMA If current therapy is LABA and blood eosinophils ≥ 300, consider adding ICS to LABA. New regimen = LABA + ICS If current therapy is LABA and blood eosinophils ≥ 100 AND ≥ 2 moderate exacerbations/1 hospitalization, consider adding ICS to LABA. New regimen = LABA + ICS
Exacerbations	LABA + ICS	Assess symptomatic benefit of	Add long-acting bronchodilator if persistent exacerbations on dual

		therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)	therapy. New regimen = LAMA + LABA + ICS If pneumonia, inappropriate indication or lack of response to ICS, consider de-escalation back to LABA + LAMA only
Exacerbations	LABA + LAMA + ICS	Assess symptomatic benefit of therapy after initiation (ie, mMRC or CAT score) Assess exacerbation history Assess inhaler technique regularly Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal)	If FEV1 <50% and presence of chronic bronchitis, consider adding roflumilast If a former or never smoker, consider adding azithromycin daily or three times a week for 12 months If pneumonia, inappropriate indication or lack of response to ICS, consider de-escalation and withdrawal of ICS

CAT, COPD assessment test; ICS, inhaled corticosteroids; LABA, long-acting beta-agonist; LAMA, long-acting muscarinic antagonists; mMRC, modified Medical Respiratory Council questionnaire; SABA, short-acting beta-agonist; SAMA, short-acting muscarinic antagonists.

TABLE 45-15

COPD Medication Chart

	Active Ingredient	Dosage Form; Route	Usual Frequency	Proprietary Name	Device Type
Short-Acting Bronchodilators					
Short-acting beta-agonist (SABA)	Albuterol sulfate	Aerosol, metered; inhalation	Four to six times a day as needed	Proventil-HFA; Ventolin-HFA; Proair HFA	MDI
	Albuterol sulfate	Solution; inhalation	Four to six times a day as needed	Accuneb; generic	Nebulization
	Levalbuterol hydrochloride	Solution; inhalation	Three to four times a day as needed	Xopenex; generic	Nebulization
	Levalbuterol tartrate	Aerosol, metered;	Three to four times a day as needed	Xopenex HFA	MDI

		inhalation			
Short-acting anticholinergics (SAMA)	Ipratropium bromide	Aerosol, metered; inhalation	Four times a day as needed	Atrovent HFA	MDI
	Ipratropium bromide	Solution; inhalation	Four times a day as needed	generic	Nebulization
Long-Acting Bronchodilators					
Long-acting beta-agonist (LABA)	Arformoterol tartrate	Solution; inhalation	Twice daily	Brovana	Nebulization
	Formoterol fumarate	Solution; inhalation	Twice daily	Perforomist	Nebulization
	Olodaterol hydrochloride	Spray metered; inhalation	Once-daily	Striverdi Respimat	SMI
	Salmeterol xinafoate	Powder; inhalation	Twice daily	Serevent Diskus	DPI
Long-acting anticholinergics (LAMA)	Aclidinium bromide	Powder; inhalation	Twice daily	Tudorza Pressair	DPI
	Tiotropium bromide	Spray metered; inhalation	Once-daily	Spiriva Respimat	SMI
	Tiotropium bromide	Powder; inhalation	Once-daily	Spiriva Handihaler	DPI
	Glycopyrrolate	Solution; inhalation	Twice daily	Lonhala Magnair	Nebulization
	Glycopyrrolate	Powder; inhalation	Twice daily	Seebri Neohaler	DPI
	Umeclidinium bromide	Powder; inhalation	Once-daily	Incruse Ellipta	DPI
	Revefenacin	Solution; inhalation	Once-daily	Yupelri	Nebulization
Inhaled Corticosteroids					
Inhaled Corticosteroids (ICS)	Beclomethasone dipropionate	Aerosol, metered; inhalation	Twice daily	Qvar Redihaler	MDI
	Budesonide	Powder;	Twice daily	Pulmicort Flexhaler	DPI

		inhalation			
	Budesonide	Suspension; inhalation	Once or twice daily	Pulmicort Respules; generic	Nebulization
	Fluticasone propionate	Aerosol, metered; inhalation	Twice daily	Flovent HFA	MDI
	Fluticasone furoate	Powder; inhalation	Twice daily	Arnuity Ellipta	DPI
	Mometasone furoate	Powder; inhalation	Twice daily	Asmanex Twisthaler	DPI
	Mometasone furoate	Aerosol; metered; inhalation	Twice daily	Asmanex HFA	MDI
Combination Inhalers					
Dual combination (SABA/SAMA)	Albuterol sulfate; ipratropium bromide	Solution; inhalation	Four to six times a day as needed	Duoneb; generic	Nebulization
	Albuterol sulfate; ipratropium bromide	Spray metered; inhalation	Four to six times a day as needed	Combivent Respimat	SMI
Dual combination (LAMA/LABA)	Umeclidium bromide; vilanterol trifenatate	Powder; inhalation	Once-daily	Anoro Ellipta	DPI
	Tiotropium bromide; olodaterol hydrochloride	Spray metered; inhalation	Once-daily	Stiolto Respimat	SMI
	Glycopyrrolate; formoterol fumarate	Aerosol, metered; inhalation	Twice daily	Bevespi Aerosphere	MDI
	Aclidinium; formoterol fumarate	Powder; metered; inhalation	Twice daily	Duaklir Pressair	DPI
Dual combination (ICS/LABA)	Budesonide; formoterol fumarate dihydrate	Aerosol, metered; inhalation	Twice daily	Symbicort	MDI
	Fluticasone furoate; vilanterol trifenatate	Powder; inhalation	Once-daily	Breo Ellipta	DPI
	Fluticasone propionate; salmeterol xinafoate	Powder; inhalation	Twice daily	Advair Diskus; Airduo Respiclick; Airduo Digihaler	DPI

	Fluticasone propionate; salmeterol xinafoate	Aerosol, metered; inhalation	Twice daily	Advair HFA	MDI
	Mometasone furoate; formoterol fumarate	Aerosol, metered; inhalation	Twice daily	Dulera	MDI
Triple combination (ICS/LAMA/LABA)	Fluticasone furoate; umeclidinium bromide; vilanterol trifenatate	Powder; inhalation	Once-daily	Trelegy Ellipta	DPI
	Budesonide; formoterol fumarate; glycopyrrolate	Aerosol; metered; inhalation	Twice daily	Breztri Aerosphere	DPI
Oral Medications					
	Roflumilast	Tablet; oral	Once-daily	Daliresp	Oral
	Theophylline	Tablet; capsule; oral	Once or twice daily (extended-release)	Theo-24; generic	Oral

Pharmacotherapy for COPD involves the use of inhaled medications that require patient knowledge and skill using various inhalation devices. Several delivery devices are available (ie, metered-dose inhalers [MDIs], dry powder inhalers [DPIs], soft-mist inhalers [SMIs], nebulizers, and ancillary devices such as holding chambers), and instructions about proper use vary (see Chapter 44, “Asthma” for information about inhalation devices). There is no clear advantage of one delivery system over another, and all devices are associated with administration errors.[41] Comorbidities common for patients with COPD, including physical and cognitive impairments, can have a significant effect on the patient’s ability to use devices, and it is recommended that patient-specific factors and preferences be considered.[1] Periodic and frequent reinforcement and observation by clinicians are required to assess optimal use and determine if alternative devices or therapy are needed.

Treatment regimens with multiple inhalation devices add complexity and may adversely impact adherence and disease management. In one cohort study, patients prescribed multiple types of inhalation devices had worse outcomes (increased exacerbations and rescue therapy use) compared to patients using devices of a similar type or administration technique.[42] For patients requiring therapy with multiple inhaled medications, clinicians should prescribe devices with a similar administration technique or containing combinations of medications. Formulary restrictions and healthcare payer reimbursement issues often make this recommendation difficult to apply in practice.

Bronchodilators

⑦ Bronchodilators represent the mainstay of drug therapy for COPD and are used to relieve patient symptoms, improve exercise tolerance, and quality of life. For patients with COPD, clinical benefits of bronchodilators include increased exercise capacity, decreased air trapping in lungs, and relief of symptoms such as dyspnea. However, the use of bronchodilators does not produce significant improvements in pulmonary function measurements of expiratory airflow such as FEV_1. Bronchodilator classes available for the treatment of COPD include short- and long-acting β_2-agonists, short- and long-acting anticholinergics, and methylxanthines. Short-acting bronchodilators relieve symptoms and increase exercise tolerance. Long-acting bronchodilators relieve symptoms, reduce exacerbation frequency, and improve quality of life and health status. In general, adverse effects of bronchodilator medications are related to their pharmacologic effects and are dose-dependent. Because COPD patients are older and more likely to have comorbid conditions, the risk for adverse effects and drug interactions is higher compared with patients with asthma.

Short-Acting Bronchodilators

The initial recommended therapy for COPD patients who experience occasional symptoms (category A) is a bronchodilator, either long- or short-acting (Tables 45-13 and 45-14). Short-acting bronchodilators are also recommended for all patients for use as rescue or as-needed therapy to manage symptoms (category A, B, C, D). Among short-acting bronchodilators, choices include short-acting β_2-agonist or short-acting anticholinergic agents. Both classes of agents have a relatively rapid onset of action, relieve symptoms, and improve exercise tolerance and lung function. Of note, short-acting bronchodilators do not reduce the frequency or severity of exacerbations in COPD. Both classes are equally effective for symptom management. When a patient does not achieve adequate management of symptoms with one agent, a combination of a short-acting β_2-agonist and short-acting anticholinergic is reasonable.

Short-Acting Sympathomimetics (β_2-Agonists)

β_2-agonists cause bronchodilation by stimulating adenyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP), which is responsible for mediating the relaxation of bronchial smooth muscle. In addition, β_2-agonists may improve mucociliary clearance within the airways. In COPD patients, short-acting β_2-agonists exert a rapid onset of effect, although response generally is less than that seen in asthma. Short-acting inhaled β_2-agonists cause only a small improvement in FEV_1 acutely but may improve respiratory symptoms and exercise tolerance despite the small improvement in spirometric measurements.

Choices for short-acting, selective β_2-agonists are albuterol and levalbuterol. Racemic epinephrine is available as an over-the-counter product but is not appropriate for chronic treatment. Albuterol is the most frequently used short-acting β_2-agonist and is a racemic mixture of (*R*)-albuterol, which is responsible for the bronchodilator effect, and (*S*)-albuterol, which has no therapeutic effect. (*S*)-Albuterol is considered by some clinicians to be inert, whereas others believe that it may be implicated in worsening airway inflammation and antagonizing the response to (*R*)-albuterol. Levalbuterol is a single-isomer formulation of (*R*)-albuterol. Despite years of clinical use, there is no compelling evidence to suggest that levalbuterol offers a clear advantage in terms of clinical effectiveness or safety over albuterol, and it is more expensive.[1]

The preferred route of administration for short-acting, selective β_2-agonists is inhalation. The use of oral and parenteral β-agonists in COPD is discouraged because they are no more effective than properly used inhalation devices, and the incidence of systemic adverse effects such as tachycardia and hand tremor is greater. Administration of β_2-agonists in outpatient and emergency room settings via inhalers (MDIs or DPIs) is at least as effective as nebulization therapy and is usually favored for reasons of cost and convenience.[1,4] Chapter 44 includes information about the devices used for delivering aerosolized medication and a comparison of β_2-agonist therapies.

Inhaled β_2-agonists are generally well tolerated. They can cause sinus tachycardia and rhythm disturbances in predisposed patients, but these are rarely reported. Skeletal muscle tremors can occur initially but generally subside as tolerance develops. Older patients may be more sensitive and may experience palpitations, skeletal muscle tremors, and “jittery” feelings after β_2-agonist use.

Short-Acting Anticholinergics

When given by inhalation, anticholinergics, also referred to as antimuscarinics, produce bronchodilation by competitively inhibiting muscarinic receptors, subtypes M_1, M_2, and M_3, in bronchial smooth muscle and mucus glands. This activity blocks acetylcholine, with the net effect being a reduction in cyclic guanosine monophosphate (cGMP), which normally acts to constrict bronchial smooth muscle and decreased mucus secretion.

Ipratropium is the most prescribed short-acting anticholinergic agent for COPD in the United States. Studies comparing ipratropium with inhaled β_2-agonists have generally reported similar improvements in pulmonary function, although ipratropium has a slower onset of action and a more prolonged bronchodilator effect. Because of the slower onset of effect (15-20 minutes compared with 5 minutes for albuterol), ipratropium may be less suitable for as-needed use; however, it is often prescribed in that manner. In contrast to albuterol, ipratropium exhibits a dose-response effect with increasing dose rather than increasing frequency. Patients may experience additional symptom improvement with a higher number of inhalations (ie, 6 puffs Q6 hours, maximum 24 puffs/day); whereas no additional improvement is seen with increasing the frequency (ie, more frequent than Q6 hours).[1]

Lack of systemic absorption of ipratropium greatly diminishes anticholinergic adverse effects such as blurred vision, constipation, urinary retention, nausea, and tachycardia associated with the prototype anticholinergic, atropine. The most frequent patient complaints with ipratropium are dry mouth, nausea, and an occasional metallic taste. In rare instances, inhaled anticholinergics may precipitate narrow-angle glaucoma symptoms. Compared to albuterol, ipratropium has a lower incidence of skeletal muscle tremor and tachycardia.

Long-Acting Bronchodilators

⑧ ⑨ For patients with COPD who experience persistent symptoms, or in whom short-acting therapies do not provide adequate relief, long-acting bronchodilator therapies are recommended (Tables 45-13 and 45-14). Long-acting agents are also recommended as initial therapy for patients at high risk for exacerbation (category C and D). Long-acting inhaled bronchodilator therapy can be administered as an inhaled β_2-agonist (LABA) or an anticholinergic (LAMA). Compared with short-acting agents, long-acting inhaled bronchodilator therapy is more convenient for patients with persistent symptoms and has shown superior outcomes in improving lung function, relieving symptoms, reducing exacerbation frequency, and improving quality of life. For symptom management, both LABAs and LAMAs are equally effective. However, LAMAs appear to be slightly more effective at preventing exacerbations. Treatment selection should consider the individual patient's response, tolerability, adherence, and economic factors.

Long-Acting Inhaled β_2-Agonists

Multiple LABAs are currently available in the United States (Table 45-15) and differ primarily by dosing frequency (twice daily vs once daily) and device type (SMI, DPI, nebulizer). One LABA, vilanterol, is currently available in the United States only in combination with an inhaled corticosteroid (fluticasone) or long-acting anticholinergic (umeclidinium). Arformoterol, formoterol, indacaterol, and olodaterol have an onset of action similar to albuterol (less than 5 minutes), whereas salmeterol has a slower onset (15-20 minutes). However, none of these agents are recommended for acute relief of symptoms in COPD. There is no dose titration for any of these agents; the starting dose is the effective and recommended dose for all patients.

Clinical benefits of LABAs compared with short-acting bronchodilators include similar or superior improvements in lung function and symptoms, as well as reduced exacerbation rates and need for hospitalization.[1] The use of the long-acting agents should be considered for patients with frequent and persistent symptoms and those at higher risk for exacerbation (see Tables 45-13 and 45-14). When patients require short-acting β_2-agonists on a scheduled basis, LABAs are more convenient based on dosing frequency but may be more expensive. In contrast to their use in asthma, LABA monotherapy for COPD is not associated with increased mortality and is recommended as part of international guidelines.

Long-acting β_2-agonists are similar with regard to the impact on disease outcomes. Salmeterol and formoterol improve lung function, symptoms, exacerbation frequency, and associated hospitalizations.[1] Indacaterol improves symptoms, health status, and frequency of exacerbations.[1] Olodaterol also decreases symptoms and improves lung function, but evidence for exacerbation outcomes is limited. Effect of olodaterol on exacerbation frequency has not been evaluated when used as monotherapy; however, when used with tiotropium, it moderately reduces exacerbations requiring systemic corticosteroids compared to tiotropium monotherapy alone.[43]

Long-Acting Anticholinergics

Several LAMAs are currently available in the United States (Table 45-15) and differ in terms of dosing frequency (twice daily vs once daily) and device type (SMI, DPI, nebulizer). Long-acting anticholinergic agents are more selective than ipratropium at blocking important muscarinic receptors. They dissociate slowly from M_3 receptors, resulting in prolonged bronchodilation with once or twice a day dosing.[44] Aclidinium, glycopyrrolate, and umeclidinium have a faster onset of action (5-15 minutes) compared to tiotropium (80 minutes); however, none of these agents are recommended for acute relief of symptoms. There is no dose titration for any of these agents; the starting dose is the effective and recommended dose for all patients.

Clinical benefits of LAMAs compared with placebo or short-acting bronchodilators include superior improvements in lung function and symptoms, as well as reduced exacerbation rates and hospitalization.[44,45] Available in the United States since 2004, tiotropium is the most extensively studied LAMA with regard to comparative outcomes. In clinical trials, aclidinium and glycopyrrolate have been shown to have similar improvements in lung function and symptoms compared to tiotropium and also reduce the frequency of exacerbations.[46–48] Clinical benefits of umeclidinium have primarily been evaluated as part of combination bronchodilator regimens.

⑧ ⑨ Long-acting anticholinergics provide similar improvements ins symptoms and health status when compared to long-acting β_2-agonists. Either class is an appropriate choice for patients with persistent symptoms or those needing a step-up from short-acting agents. When evaluating exacerbation outcomes, LAMAs (primarily tiotropium) provide a greater reduction in exacerbation frequency compared to LABAs and should be considered as first-line monotherapy for patients at high risk for exacerbation (Tables 45-13 and 45-14).

Long-acting anticholinergics have been evaluated in clinical trials to determine the potential impact of bronchodilator therapy on the progression of lung function decline. In the landmark clinical trial understanding potential long-term impacts on function with tiotropium (UPLIFT), patients were randomized to therapy with either placebo or inhaled tiotropium, and lung function decline was followed for 4 years.[49] Tiotropium was not shown to have significant effect on lung function decline over time but was effective for reducing symptoms and frequency of exacerbations. Patients in this trial were in more advanced stages of COPD as reflected by the mean postbronchodilator FEV_1 of 1.32 L, corresponding to 48% of predicted FEV_1 or GOLD spirometric stage 3. More recently, tiotropium has again been evaluated for its effect on lung function, but this time in patients in earlier stages of the disease. In the Tie-COPD trial, patients with an FEV_1 >50% of predicted (GOLD spirometric grade 1 or 2) were randomized to placebo or tiotropium, and lung function decline followed for 2 years.[50] At the end of the trial, patients in the tiotropium group had a higher measured FEV_1 and slower annual decline compared to patients in the placebo group. Application of these results to clinical practice may be difficult given that current goals for inhaled therapy are targeted at patients with symptoms or those at high risk of future exacerbation. Slowing lung function has not yet been a therapeutic target with inhaled therapy. If used in early-stage disease, it would require patients who do not yet have symptoms or experienced an exacerbation to commit to long-term maintenance therapy. Future studies are needed to determine optimal timing and length of bronchodilator therapy.

Previously, retrospective analyses have reported an increased risk of cardiovascular events associated with ipratropium and tiotropium use.[51] However, the UPLIFT study, which was a prospective trial over 4 years, did not report an increased cardiovascular risk associated with tiotropium use.[49] Additionally, a prospective, noninferiority trial (TIOSPIR) has been published which compared the effects of tiotropium delivered via Handihaler or Respimat devices among 17,000 patients with COPD over a median 2.3-year period.[52] Primary outcomes in this trial were risk of death and risk of first COPD exacerbation. Secondary outcomes included cardiovascular safety. No significant differences were seen in any of the primary or secondary outcomes when comparing tiotropium delivery devices. Further studies are needed to evaluate the cardiovascular safety of ipratropium.

Combination Anticholinergics and β-Agonists (Dual Bronchodilators)

Combination regimens of bronchodilators are often used in the treatment of COPD as symptoms worsen over time. Combining bronchodilators with different mechanisms of action allows the lowest possible effective doses to be used and reduces potential adverse effects from individual agents.[1] Short-acting bronchodilators may be combined for patients experiencing persistent symptoms, although step-up to long-acting bronchodilator monotherapy is usually preferred (Tables 45-13 and 45-14).

Current clinical practice guidelines recommend combining long-acting bronchodilators for patients who have persistent symptoms or recurrent exacerbations on bronchodilator monotherapy (Tables 45-13 and 45-14). Combination of long-acting bronchodilators (LAMA/LABA) provides significant improvement in lung function, symptoms, and quality-of-life measures compared with LABA or LAMA monotherapy.[1,53] In addition, dual long-acting bronchodilator therapy has been shown to decrease the frequency of moderate-to-severe exacerbations compared to either LAMA or LABA monotherapy.

Methylxanthines

Methylxanthines, including theophylline and aminophylline, may produce bronchodilation through numerous mechanisms, including (a) inhibition of phosphodiesterase, thereby increasing cAMP levels, (b) inhibition of calcium ion influx into smooth muscle, (c) prostaglandin antagonism, (d) stimulation of endogenous catecholamines, (e) adenosine receptor antagonism, and (f) inhibition of release of mediators from mast cells and leukocytes.[1] Chronic theophylline use for patients with COPD may offer improvements in lung function and gas exchange. Subjectively, theophylline has been shown to reduce dyspnea, increase exercise tolerance, and improve respiratory drive in COPD patients.[1]

Methylxanthines have been available for the treatment of COPD for at least five decades and at one time were considered first-line therapy. However, with the availability of LABAs and LAMAs, the role of methylxanthine therapy has become more limited. Because of the risk for drug interactions and significant intrapatient and interpatient variability in dosage requirements, theophylline therapy generally is considered for patients who are intolerant or unable to use an inhaled bronchodilator. Theophylline is considered an alternative to commonly used inhaled therapies for bronchodilation and improving symptoms.[1] However, the evidence does not support the use of theophylline to prevent exacerbations.[54]

Although theophylline is available in a variety of oral dosage forms, sustained-release preparations are most appropriate for the long-term management of COPD. These products have the advantage of improving medication adherence and achieving more consistent serum concentrations over rapid-release theophylline and aminophylline preparations. However, caution must be used in switching from one sustained-release preparation to another because there is considerable variability in their sustained-release characteristics.

Therapy can be initiated at 200 mg twice daily and titrated upward every 3 to 5 days to the target dose. Most patients require daily doses of 400 to 900 mg. Dosage adjustments generally should be made based on serum concentration results. Traditionally, the therapeutic range of theophylline has been 10 to 20 mcg/mL (mg/L; 55-111 μmol/L); however, because of the frequency of dose-related adverse effects and a lack of a clear benefit when used in higher concentrations, a more conservative therapeutic range of 8 to 15 mcg/mL (mg/L; 44-83 μmol/L) is now targeted, especially in the elderly. When concentrations are measured, trough measurements should be obtained.

Once a dose is established, serum concentrations should be monitored once or twice a year unless the patient's disease worsens, medications that interfere with theophylline metabolism are added to therapy, or toxicity is suspected. Adverse effects are dose-related; however, there is an overlap between therapeutic and toxic ranges. Minor adverse effects include dyspepsia, nausea, vomiting, diarrhea, headache, dizziness, and tachycardia. More serious toxicities, which typically do not occur until concentrations exceed 20 mcg/mL (mg/L; 111 μmol/L), include arrhythmias and seizures.

Factors that decrease theophylline clearance and lead to reduced maintenance dose requirements include advanced age, bacterial or viral pneumonia, left or right ventricular failure, liver dysfunction, hypoxemia from acute decompensation, and use of drugs such as cimetidine, macrolides, and fluoroquinolone antibiotics. Factors that may enhance theophylline clearance and result in the need for higher maintenance doses include tobacco and marijuana smoking, hyperthyroidism, and the use of such drugs as phenytoin, phenobarbital, and rifampin.

Theophylline is a challenging medication to dose, monitor, and manage due to the significant intrapatient and interpatient variability in pharmacokinetics and the potential for drug interactions and toxicities. Consequently, inhaled bronchodilator therapy is currently preferred based on superior efficacy and safety, as well as ease of use. Current guidelines recommend theophylline only when inhaled bronchodilators are unavailable or unaffordable.[1]

Corticosteroids

Anti-inflammatory mechanisms whereby corticosteroids exert their beneficial effect in COPD include: (a) reduction in capillary permeability to decrease mucus, (b) inhibition of release of proteolytic enzymes from leukocytes, and (c) inhibition of prostaglandins. The benefits of chronic systemic corticosteroid therapy in the chronic management of COPD are not clear, and the risk of toxicity is significant. Long-term adverse effects associated with systemic corticosteroid therapy include osteoporosis, muscular atrophy, thinning of the skin, development of cataracts, and adrenal suppression and insufficiency. Therefore, chronic therapy with oral steroids should be avoided in COPD patients.[1] While a small number of COPD patients are responders to oral steroids, many of these patients may have an asthmatic, or reversible, component to their disease. Asthma-COPD overlap syndrome (ACOS) is now a recognized condition affecting both asthma and COPD patients, and patients exhibiting this syndrome may benefit from therapies traditionally considered for asthma alone.[19] Inhaled corticosteroids may be considered in patients with chronic stable COPD who are at high risk of exacerbation (category C or D) and used short-term as systemic therapy for acute exacerbations (Tables 45-13, 45-14, and 45-22).

⑩ It has been postulated that inhaled corticosteroid therapy might be beneficial in COPD to slow disease progression. Unfortunately, the results of major clinical trials have failed to demonstrate any clear benefit from chronic treatment with ICS in modifying long-term decline in lung function.[1] ICS have been associated with improvements in clinical endpoints related to exacerbations, including a decrease in exacerbation frequency and time to first exacerbation.[1,55] Clinical benefits of ICS therapy in COPD have been observed with combination therapy, primarily as an addition to LABA monotherapy. Given the lack of supporting evidence and in contrast to evidence in patients with asthma, ICS monotherapy for patients with COPD is not recommended.

Although a dose-response relationship for ICS has not been demonstrated in COPD, initial clinical trials employed moderate-to-high doses for chronic treatment. At these doses, adverse effects must be considered with long-term therapy. Recent trials have reported an increased risk of pneumonia and mycobacterial pulmonary infections in patients with COPD who receive inhaled corticosteroids, and there is increasing recognition for utilizing lower doses of ICS and withdrawing therapy in selected patients.[55–57] Risk factors for developing pneumonia include age >55 years, body mass index (BMI) less than 25 kg/m^2, current smoker, history of exacerbation or pneumonia (last 12 months), or severe airflow limitation.[1] Other adverse effects associated with inhaled corticosteroids include hoarseness, sore throat, oral candidiasis, and skin bruising. Severe adverse effects, such as adrenal suppression, osteoporosis, and cataract formation, have been reported less frequently than with systemic corticosteroids, but clinicians should monitor patients who are receiving high-dose chronic inhaled therapy.

There has been conflicting evidence supporting a dose relationship between ICS use and risk of fractures among patients with COPD. A recent nested, case-control analysis of over 200,000 patients observed an increased risk of fracture with higher daily doses of ICS and long-term use (>4 years).[58] Given this evidence, it appears prudent to treat patients with the lowest effective dose of ICS to minimize the risk of fracture. Clinicians should also recommend adequate intake of calcium and vitamin D and consider periodic bone mineral density testing for patients at risk of osteopenia.

ICS therapy is recommended for initial treatment in patients at high risk of exacerbation and with a blood eosinophil count greater than 300 cells per microliter (category D).[1] For escalation therapy, inhaled corticosteroids may be considered for patients who have recurrent exacerbations despite optimal therapy with inhaled bronchodilators (Table 45-14). Given the risks associated with long-term ICS therapy, clinicians should appropriately identify patients who will receive the best benefit, and patient-specific factors should be considered when making the decision to initiate ICS therapy (Table 45-16). Evaluations of current practice have shown that many patients with COPD may be inappropriately prescribed an ICS (ie, not high risk for exacerbations nor elevated blood eosinophil count), exposing them to unnecessary adverse effects.[59,60]

TABLE 45-16

Considerations for Initiating Inhaled Corticosteroid Therapy in COPD

Recommend ICS Initiation	Consider ICS Initiation	Recommend Against ICS Initiation
History of hospitalization(s) for acute exacerbation of COPD despite appropriate long-acting bronchodilator therapy Two or more moderate exacerbations of COPD per year despite appropriate long-acting bronchodilator therapy Blood eosinophils greater than 300 cells/μL(0.3 x 10^9/L) History of or concomitant asthma	One moderate exacerbation of COPD per year despite appropriate long-acting bronchodilator therapy Blood eosinophils between 100 and 300 cells/μL(0.1 x 10^9/L - 0.3 x 10^9/L)	Repeated pneumonia events Blood eosinophils less than 100 cells/μL(0.1 x 10^9/L) History of mycobacterial infection

ICS, inhaled corticosteroid

Given concern for increased pulmonary infections among patients treated with ICS and growing evidence for benefit of dual bronchodilator therapy, clinicians have advocated for withdrawing ICS therapy in selected patients (Table 45-17). Recent trials have reported that ICS can be safely withdrawn from combination ICS/LABA therapy in patients with no initial indication for ICS (ie, FEV1 >50% and low risk of exacerbation), without an increase in exacerbation frequency.[60] For patients with more severe disease or at high risk of exacerbation, ICS may also be safely withdrawn from combination ICS/LABA/LAMA therapy in selected situations. These situations may include patients experiencing adverse effects, such as recurrent pneumonia, or those who do not appear to benefit from ICS therapy. For patients with blood eosinophil counts greater than 300 cells/μL (0.3 x 10^9/L), the benefit of continuing ICS therapy may outweigh the risk of adverse effects.

TABLE 45-17

Considerations for Withdrawing Inhaled Corticosteroid Therapy in COPD

Recommend ICS Withdrawal	Consider ICS Withdrawal	Recommend Against ICS Withdrawal
Patients initiated on ICS therapy with no clear guideline-based indication Patients experiencing adverse effects with ICS therapy and limited therapeutic benefit Patients experiencing no perceived therapeutic benefit with ICS Blood eosinophils less than 100 cells/μL(0.1 x 10^9/L)	Patients experiencing adverse effects with ICS therapy and some therapeutic benefit Blood eosinophils between 100 and 300 cells/μL(0.1 x 10^9/L - 0.3 x 10^9/L)	Blood eosinophils greater than 300 cells/μL(0.3 x 10^9/L) History of concomitant asthma

ICS = inhaled corticosteroid

Combination Therapy: Dual Therapy (LAMA/LABA or ICS/LABA)

For most patients with recurrent exacerbations despite optimal long-acting bronchodilator monotherapy, combination therapy with dual long-acting bronchodilators (LAMA/LABA) is preferred over combination therapy with ICS/LABA (Table 45-14).[1,61] This recommendation is based on results of the FLAME trial which reported superior efficacy with regard to exacerbation prevention with LAMA/LABA (glycopyrrolate/indacaterol) therapy compared to ICS/LABA (fluticasone/salmeterol) and a lower rate of pneumonia (3.2% for LAMA/LABA vs 4.8% for ICS/LABA).[6,62] Subgroup analyses of several trials have indicated that patients with elevated sputum and blood eosinophil counts and those with concomitant asthma have greater therapeutic benefit with ICS therapy compared to other patients.[63] Consequently, guidelines recommend combination therapy with ICS/LABA instead of LAMA/LABA for patients with blood eosinophil ≥ 300 cells/μL (0.3 × 10^9/L) or ≥ 100 cells/μL (0.1 x 10^9/L)and ≥ two moderate exacerbations or one exacerbation requiring hospitalization in the last year (high risk).[1]

A more recent study appears to contradict the superiority of LAMA/LABA over ICS/LABA for exacerbation prevention. In the IMPACT trial, which was a three-arm study designed to evaluate the benefit of escalation to triple therapy (LAMA/LABA/ICS) versus dual therapy with ICS/LABA or LAMA/LABA, exacerbation prevention was greater in the ICS/LABA group compared to the LAMA/LABA group.[64] While these results are in contrast to the outcomes of the FLAME trial, 70% of patients enrolled in the IMPACT trial were already receiving ICS prior to randomization and the run-in period after randomization was only 2 weeks. Thus, patients on ICS and randomized to the LAMA/LABA group effectively discontinued ICS therapy without tapering and may account for the higher number of exacerbations seen initially after randomization. Additionally, patients with asthma were not excluded from this study, which may account for the lower exacerbation rate observed in the ICS/LABA group compared to the LAMA/LABA group.

Combination Therapy: Triple Therapy (LAMA/LABA/ICS)

For patients with persistent symptoms and recurrent exacerbations on dual inhaled therapy, triple therapy with LAMA/LABA/ICS is recommended as initial escalation therapy for patients with blood eosinophil counts greater than 100 cells/μL (0.1 x 10^9/L) (Table 45-14). Evidence for the benefit of triple therapy has emerged from recent studies evaluating combination therapy within a single device, and there is also limited evidence supporting triple therapy given by multiple devices.[64–67] Compared to dual therapy with either LAMA/LABA or ICS/LABA, triple therapy with LAMA/LABA/ICS provides additional benefit in reducing the frequency of moderate-to-severe exacerbations in patients with COPD. Given the risk of adverse effects with ICS, clinicians may consider bypassing triple inhalation therapy (LAMA/LABA/ICS) for those patients with persistent exacerbations and lower blood eosinophil count (<100 cells/μL [0.1 × 10^9/L]) in favor of oral alternatives such as roflumilast or azithromycin.[1]

Post-hoc analyses from two recent trials have reported a potential association between triple therapy with LAMA/LABA/ICS and reduction in mortality.[68,69] Early information suggests that the addition of ICS may provide a survival benefit when compared to combination therapy with LAMA/LABA alone in some patients. Definitive causation and conclusions cannot yet be determined until more prospective studies are conducted. As has been seen with therapeutic outcomes from ICS treatment in COPD patients, it is likely that any potential survival benefit may vary based on patient-specific factors and considerations.

Phosphodiesterase Inhibitors

Phosphodiesterase 4 (PDE4) is the major phosphodiesterase found in airway smooth muscle cells and inflammatory cells and is responsible for degrading intracellular cAMP. Inhibition of PDE4 results in relaxation of airway smooth muscle cells and diminished inflammatory mediators such as TNF-α and IL-8. Roflumilast, an oral PDE4 inhibitor available in the United States, is recommended for patients with recurrent exacerbations despite treatment with triple inhalation therapy (LAMA/LABA/ICS) (Table 45-14).[1] It may also be considered as escalation therapy for patients with recurrent exacerbations on dual long-acting bronchodilators (LAMA/LABA) who are not candidates for ICS, such as those with low blood eosinophil count (<100 cells/μL [0.1×10^9/L]) or who are at higher risk of adverse effects associated with ICS. Given both theophylline and roflumilast have similar mechanisms of action through inhibition of phosphodiesterases, both should not be used together for the management of COPD.

Roflumilast has bothersome adverse effects that may limit therapy in some patients.[70] Major effects include diarrhea, nausea, decreased appetite, weight loss, headache, and neuropsychiatric effects such as suicidal thoughts, insomnia, anxiety, and new or worsened depression. Most symptoms such as diarrhea, nausea, and headache occur early after initiation and usually resolve over time. The starting dose should be 250 mcg orally for 4 weeks and then increase to a maintenance dose of 500 mcg orally once a day to avoid adverse effects that may lead to early discontinuation of therapy. Weight loss (average of 2 kg) may be of concern in patients with low BMI, and discontinuation may be necessary if significant weight loss is observed. The use of roflumilast is cautioned in patients with a history of depression or suicidality. Both patients and family members should be counseled regarding the potential for mood and behavior changes and to alert healthcare providers if they occur.

Roflumilast is metabolized by CYP3A4 and 1A2, and coadministration with strong inducers of cytochrome P450 is not recommended due to the potential for subtherapeutic plasma concentrations. Although there are no recommended dose adjustments, caution should also be used when administering roflumilast with strong inhibitors of cytochrome P450 due to the potential for adverse effects.

Azithromycin

In certain pulmonary conditions such as cystic fibrosis and bronchiectasis, chronic therapy with macrolide antibiotics, specifically azithromycin, has proven clinical benefit due to their anti-inflammatory and antimicrobial properties. Studies evaluating chronic azithromycin therapy (either 250 mg orally daily or 500 mg orally three times a week for 12 months) in patients with COPD have reported lower rates of exacerbations among treated patients.[71,72] In a subgroup analysis, patients who continued to smoke did not have a reduction in exacerbation frequency with azithromycin. Therapy with azithromycin was associated with a higher rate of colonization with macrolide-resistant bacteria and hearing deficits. In 2012, a retrospective, observational study reported an increase in cardiac events with short courses of azithromycin.[73] The Food and Drug Administration (FDA) has since updated product labeling to include a precaution about QT prolongation.

Given limited evidence supporting the use of long-term treatment with azithromycin, it would be prudent to wait for more safety data before routinely recommending this therapy for more than 12 months in patients with COPD who are at high risk for exacerbations. Current guidelines recommend considering the addition of chronic azithromycin for patients with recurrent exacerbations despite optimal therapy and who are not active smokers (Table 45-14). Clinicians may choose to consider azithromycin for individual patients at high risk for exacerbations but must carefully weigh the risks and benefits of therapy.

α_1-Antitrypsin Replacement Therapy

For patients with inherited AAT deficiency (AATD)–associated emphysema, treatment focuses on the reduction of risk factors such as smoking, symptomatic treatment with bronchodilators, and augmentation therapy with replacement AAT. Based on knowledge about the relationship between serum concentrations of AAT and the risk of developing emphysema, augmentation therapy is intended to maintain serum concentrations above the protective threshold throughout the dosing interval.[1,17] Augmentation therapy consists of weekly infusions of pooled human AAT to maintain AAT plasma levels over 10 μmol/L (0.54 g/L). Much of the data supporting the use of AAT replacement are based on evidence of biochemical efficacy (eg, administering the product and demonstrating protective serum concentrations of AAT).

Clinical evidence for slowing lung function decline or improving outcomes with augmentation therapy is sparse. Stated challenges to performing randomized clinical trials include the large sample size and long duration of follow-up required, and the expense of conducting such a trial. A systematic review of available trials found an association between intravenous augmentation therapy and reduction in disease progression, as measured by computed tomography (CT) density, and decrease in exacerbation frequency.[74] Augmentation therapy with AAT remains the mainstay of treatment for patients with AATD-associated lung disease.

The recommended dosing regimen for replacement AAT is 60 mg/kg administered IV once a week at a rate of 0.08 mL/kg/min, adjusted to patient tolerance. Augmentation therapy can cost over $50,000 annually. In the absence of alternative treatments, it is difficult to assess the cost-effectiveness using conventional criteria. Based on the high cost and limited availability of therapy in some countries, consensus guidelines have suggested that therapy be considered for patients with an FEV1 35% to 60% predicted. AAT replacement therapy is derived from pooled blood donors. There have been repeated problems with the supply of this product due to production and contamination issues. There are several products available, which should minimize interruption in product supply in the future. Development of recombinant products and AAT replacement via inhalation continues.

Other Pharmacologic Considerations

Several other treatments have been explored over the years. Among these therapies, either there is insufficient evidence to warrant recommending their use, or they have been proven to not be beneficial in the management of COPD. A summary is provided because the clinician likely will encounter patients who are receiving or inquire about these treatments.

Expectorants, Mucolytics, and Antioxidants

Adequate water intake generally is sufficient to maintain hydration and assist in the removal of airway sections. Mucolytics and expectorants such as N-acetylcysteine and guaifenesin have been evaluated as adjunctive therapy for patients with COPD. In one trial, patients with moderate-to-severe COPD were randomized to either placebo or oral N-acetylcysteine 600 mg twice daily for 1 year. Patients were not required to be on ICS prior to randomization. N-acetylcysteine was associated with a significant decrease in exacerbation rate among patients with moderate disease only.[75] Strong evidence of clinical benefit is lacking for the routine use of mucolytics in the treatment of COPD.[76]

In 2011, FDA removed unapproved cough and cold preparations, including several containing guaifenesin, from the market due to safety and efficacy concerns. Several extended-release tablet formulations are currently approved by the FDA. Other approved formulations of guaifenesin contain dextromethorphan or pseudoephedrine and should not be used for COPD maintenance therapy.

Opioids

Systemic (oral and parenteral) opioids, especially morphine, can relieve dyspnea for patients with end-stage COPD. Nebulized therapy is sometimes used in clinical practice, although data about clinical benefit are lacking. Opioids should be used carefully, if at all, to avoid reducing ventilatory drive.

Emerging Therapies

Based on knowledge about the importance of neutrophilic inflammation in COPD and potential therapeutic benefit of inhibition of neutrophil activity, several anti-inflammatory compounds have been explored. Many studies of these strategies have been disappointing or report inconsistent results. Therapy with mepolizumab, an anti-interleukin 5 antibody, and benralizumab, an anti-interleukin 5 receptor-alpha antibody, has been shown to decrease exacerbations among COPD patients and may be associated with a greater effect among patients with elevated blood eosinophils.[1] Other current areas of investigation immunoglobulin E, inhibitors of interleukin 5, interleukin 4, interleukin 13, and tyrosine kinases.[77]

The role of HMG-CoA reductase inhibitors for patients with COPD has garnered interest due to known pleiotropic effects statins and the role of systemic inflammation in COPD. Retrospective and observational trials have reported previous associations with simvastatin therapy and reduction in exacerbation frequency, although this effect was not confirmed in a prospective, randomized trial.[78]

In a meta-analysis of trials, vitamin D supplementation for patients with COPD and low baseline levels of 25-hydroxyvitamin D (less than 25 nmol/L [10 ng/mL]) significantly reduced the rate of moderate and severe exacerbations but was not associated with a reduction in exacerbations in patients with levels of 25-hydroxyvitamin D greater than 25 nmol/L (10 ng/mL).[79] Given the low cost and multiple benefits of vitamin D supplementation, it is recommended to check 25-hydroxyvitamin D concentrations for patients hospitalized with AECOPD and supplement if below 25 nmol/L (10 ng/mL).[1]

ACUTE EXACERBATION OF COPD

Pathophysiology

The natural history of COPD is characterized by recurrent acute exacerbations associated with increased symptoms and a decline in overall health status. An exacerbation is defined as a change in the patient's baseline symptoms (dyspnea, cough, or sputum production) beyond day-to-day variability sufficient to warrant a change in management.[1] Exacerbations have a significant impact on the natural course of COPD and occur more frequently in patients with advanced age, significant airflow limitation, and comorbid conditions. Because many patients experience chronic symptoms, diagnosis of an exacerbation is based, in part, on subjective measures and clinical judgment; thus, it can be considered a syndrome. Exacerbations are significant events associated with significant morbidity, including worsening health status, increased risk for acute cardiovascular events, impairment of daily activities, and acceleration of lung function decline. Additionally, exacerbations, especially those requiring hospitalization, are associated with increased mortality risk. Acute exacerbations have a significant impact on the economics of treating COPD, estimated at 35% to 45% of the total costs of the disease in some settings.[2–4]

There is limited data about the pathophysiology of COPD exacerbation due to the chronic nature of the disease and the poor health of patients. Inflammatory mediators, including neutrophils and eosinophils, may be increased in sputum during an exacerbation. Airflow limitation may not change remarkably during an exacerbation compared to chronic baseline limitation.[1] Lung hyperinflation, if present, is worsened during an exacerbation, which contributes to increasing dyspnea and poor gas exchange.

The primary physiologic change is often a worsening of ABG values due to poor gas exchange and increased muscle fatigue. For a patient experiencing a severe exacerbation, profound hypoxemia and hypercapnia can be accompanied by respiratory acidosis and respiratory failure.

Criteria used to define acute exacerbation of COPD (AECOPD) among clinicians vary widely; however, most rely on a change in one or more of the following clinical findings: worsening symptoms of dyspnea, increase in sputum volume, or purulence (Table 45-18). With an exacerbation, patients using rapid-acting bronchodilators may report an increase in the frequency of use and may seek additional medical care. Acute exacerbations can range from mild to severe and are classified based on the level of treatment and intervention required (Table 45-19).

TABLE 45-18

Staging Acute Exacerbations of COPD[a]

Mild (type 1)	One cardinal symptom[a] plus at least one of the following: URTI[b] within 5 days, fever without other explanation, increased wheezing, increased cough, increase in respiratory or heart rate >20% above baseline
Moderate (type 2)	Two cardinal symptoms[a]
Severe (type 3)	Three cardinal symptoms[a]

[a] Cardinal symptoms include worsening of dyspnea, increase in sputum volume, and increase in sputum purulence.

[b] URTI, upper respiratory tract infection.

TABLE 45-19

Classification of Acute Exacerbation of COPD

Severity	Definition
Mild	Treated with short-acting bronchodilators only No treatment with antibiotics or systemic corticosteroids required
Moderate	Treated with short-acting bronchodilators Treatment with antibiotics and/or systemic corticosteroids required
Severe	Treated with short-acting bronchodilators Treatment with antibiotics and/or systemic corticosteroids required Treatment requires hospitalization or a visit to an emergency department May be associated with acute respiratory failure

An important complication of a severe exacerbation is acute respiratory failure. In the emergency department or hospital, an ABG usually is obtained to assess the severity of an exacerbation. The diagnosis of acute respiratory failure in COPD is made based on an acute change in the ABGs. Defining acute respiratory failure as a PaO_2 of less than 50 mm Hg (6.7 kPa) or a $PaCO_2$ of greater than 50 mm Hg (6.7 kPa) often may be incorrect and inadequate because these values may not represent a significant change from a patient's baseline values. A more precise definition is an acute drop in PaO_2 of 10 to 15 mm Hg (1.3-2.0 kPa) or any acute increase in $PaCO_2$ that decreases the serum pH to 7.3 or less. Additional acute clinical manifestations of respiratory failure include restlessness, confusion, tachycardia, diaphoresis, cyanosis, hypotension, irregular breathing, miosis, and unconsciousness.

Clinical Presentation

CLINICAL PRESENTATION: COPD Exacerbations

Symptoms

- Increased sputum volume
- Acutely worsening dyspnea
- Chest tightness
- Presence of purulent sputum
- Increased need for bronchodilators
- Malaise, fatigue
- Decreased exercise tolerance

Physical Examination

- Fever
- Wheezing, decreased breath sounds

Diagnostic Tests

- Sputum sample for Gram stain and culture
- Chest radiograph to evaluate for new infiltrates

Prognosis

AECOPD are associated with significant morbidity and mortality. While mild exacerbations may be managed at home, mortality rates are higher for patients admitted to the hospital with the highest rates among those admitted to the intensive care unit. COPD exacerbations contribute to in-hospital mortality, deaths after discharge, and the decline of lung function. Many patients experiencing an exacerbation do not return to their baseline clinical status for several weeks, significantly affecting their quality of life.

As many as 50% of patients hospitalized for an exacerbation are readmitted within 6 months.[2–4] Risk factors for relapse and potential readmission include FEV_1 less than 50% of predicted, the severity of exacerbation, previous exacerbation frequency, presence of comorbidities, and inadequate antibiotic therapy.[80] As part of the 2010 Affordable Care Act, the Hospital Readmission Reduction Program was established by the Centers for Medicare & Medicaid Services (CMS) that incentivize healthcare organizations to reduce readmission rates for selected conditions, including COPD. The most important predictor for a future exacerbation is past exacerbation history; thus, prevention of AECOPD is a major therapeutic goal for patients with a history of frequent exacerbations (ie, high risk).

TREATMENT: COPD EXACERBATIONS

Desired Outcomes

⑪ The goals of therapy for patients experiencing AECOPD are to minimize the negative consequences of the acute exacerbation (ie, reduce symptoms, prevent hospitalization, shorten hospital stay, prevent acute respiratory failure or death), and prevent future exacerbations.[1] Factors that influence severity, and subsequently the level of care required, include the severity of airflow limitation, presence of comorbidities, and history of previous exacerbations. Table 45-20 includes factors that warrant treatment in the hospital, and Table 45-21 describes the assessment of hospitalized patients for the presence of acute respiratory failure.

TABLE 45-20

Factors Favoring Hospitalization for Treatment of COPD Exacerbation

- Presence of high-risk comorbidity (eg, pneumonia, arrhythmia, CHF, diabetes, renal or hepatic failure)
- Suboptimal response to outpatient management
- Marked worsening of dyspnea
- Inability to eat or sleep due to symptoms
- Worsening hypoxemia or hypercapnia
- Mental status changes
- Lack of home support for care
- Uncertain diagnosis

TABLE 45-21

Assessment of Patients Hospitalized for Acute Exacerbations of COPD

Assessment	Presentation
No respiratory failure	Respiratory rate 20-30 bpm No use of accessory muscles No changes in mental status Hypoxemia improved with supplemental oxygen No increase in $PaCO_2$
Acute respiratory failure—not life-threatening	Respiratory rate >30 bpm Using accessory muscles No changes in mental status Hypoxemia improved with supplemental oxygen Increase in $PaCO_2$ compared to baseline or 50-60 mm Hg (6.7-8.0 kPa)
Acute respiratory failure—life-threatening	Respiratory rate >30 bpm Using accessory muscles Acute changes in mental status Hypoxemia not improved with supplemental oxygen or need for FIO_2 >40% (0.40) Increase in $PaCO_2$ compared to baseline or >60 mm Hg (8.0 kPa) or acidosis (pH < 7.25)

bpm, beats per minute

Various therapeutic options for exacerbation management are summarized in Table 45-22. Pharmacotherapy consists of intensification of bronchodilator therapy and a short course of systemic corticosteroids. Antimicrobial therapy is indicated in the presence of selected symptoms. Since the frequency and severity of exacerbations are closely related to each patient’s overall health status, all patients should receive optimal chronic treatment, including smoking cessation, appropriate pharmacologic therapy, and preventative therapy such as vaccinations.

TABLE 45-22

Therapeutic Options for Acute Exacerbations of COPD

Therapy	Comments
Antibiotics	Recommended if all three of the following cardinal symptoms are present: ○ Increased dyspnea ○ Increased sputum production ○ Increased sputum purulence Recommended if at least two of the following cardinal symptoms are present as long as one of the symptoms is increased sputum purulence: ○ Increased dyspnea ○ Increased sputum production ○ Increased sputum purulence Recommended for patients requiring mechanical ventilation (either noninvasive or invasive) regardless of symptoms present Recommended treatment duration is 5-7 days
Corticosteroids	Oral or IV therapy may be used for a total duration of 5-7 days. If IV is used, it should be changed to oral after improvement in pulmonary status. Longer courses of therapy are associated with increased risk of pneumonia and adverse effects
Bronchodilators	MDIs and DPIs equal in efficacy to nebulization β-Agonists also may increase mucociliary clearance Long-acting β-agonists or long-acting antimuscarinics should not be used for quick relief of symptoms or on an as-needed basis
Controlled oxygen therapy	Titrate oxygen to desired oxygen saturation (>90% [0.90]) Monitor arterial blood gas for the development of hypercapnia
Noninvasive mechanical ventilation	Consider for patients with acute respiratory failure Not appropriate for patients with altered mental status, severe acidosis, respiratory arrest, or cardiovascular instability

Nonpharmacologic Therapy

Noninvasive positive-pressure ventilation (NPPV) provides ventilatory support with oxygen and pressurized airflow using a face or nasal mask with a tight seal but without endotracheal intubation. There have been numerous trials reporting the benefits of NPPV for patients with acute respiratory failure due to COPD exacerbations. NPPV has been associated with lower mortality, lower intubation rates, and shorter hospital stays for COPD exacerbations. A recent analysis regarding NPPV in patients with respiratory failure, in general, included a subset of patients with COPD and reported that the risk of hospital-based mortality and long-term mortality was reduced by 56%.[81] Benefits seen with NPPV generally can be attributed to a reduction in the complications that often arise with invasive mechanical ventilation. Not all patients with COPD exacerbations are appropriate candidates for NPPV. Patients with altered mental status may not be able to protect their airway and thus may be at increased risk for aspiration. Patients with severe acidosis (pH <7.25), respiratory arrest, or cardiovascular instability should not be considered for NPPV. Patients who fail a trial of NPPV or those considered poor candidates should be considered for intubation and mechanical ventilation if appropriate based on the patient's goals of care.

Pharmacologic Therapy

Bronchodilators

During exacerbations, intensification of bronchodilator regimens is used commonly. Short-acting β_2-agonists are preferred due to their rapid onset of action. The doses and frequency of bronchodilator administration can be increased to provide symptomatic relief. Anticholinergic agents may be added if symptoms persist despite increased doses of β_2-agonists. Combinations of these agents are often employed, although data are lacking about their benefit versus using higher doses of a single agent. Bronchodilators may be administered via MDIs or nebulization with equal efficacy.[1] Nebulization may be considered for patients with severe dyspnea who cannot hold their breath after the actuation of an MDI. Evidence supporting the use of theophylline during exacerbations is lacking, and thus theophylline generally should be avoided due to concern for adverse effects.

Corticosteroids

Treatment with systemic corticosteroids in AECOPD has been shown to improve oxygenation, recovery time, shorten hospitalization, and reduce the risk of relapse.[4,82] Studies have varied with regards to the severity of exacerbation (ie, moderate or severe), clinical setting (ie, outpatient management or hospitalization), and dosing regimen (ie, dose, route, frequency, and duration). Several trials enrolling hospitalized patients have used high initial doses (often intravenous) before tapering to a lower oral dose to complete the duration of therapy. Adverse effects such as hyperglycemia, insomnia, and hallucinations may occur at higher doses. Depending on the patient's clinical status, treatment may be initiated at a lower dose or tapered more quickly if these effects occur.

The optimal corticosteroid dosing regimen for each presentation of AECOPD is unknown. However, a regimen of prednisone 40 mg orally daily (or equivalent) for 5 days can be effective for most patients. The REDUCE trial evaluated a 5-day course of prednisone 40 mg versus 14 days in a noninferiority study.[83] Shorter treatment duration was noninferior to longer treatment duration for the primary outcome of time to next exacerbation and resulted in less systemic corticosteroid exposure. Longer courses of systemic steroids have been associated with increased risk of pneumonia, hospitalization, and all-cause mortality, and shorter courses (5-7 days) are preferred to avoid adverse effects.[84] Areas of emerging evidence in the treatment of AECOPD include using nebulized corticosteroid (budesonide) rather than systemic administration and correlation of blood eosinophil counts and benefits of therapy.[1]

Antimicrobial Therapy

⑫ Viral or bacterial infections cause most AECOPD. However, as many as 30% of exacerbations are caused by unknown factors.[1] Data supporting the use of antibiotics for COPD exacerbations are remarkably sparse. To limit unnecessary use, antibiotics should be initiated in any of these clinical situations: (1) patients presenting with three cardinal symptoms of AECOPD, (2) patients presenting with two cardinal symptoms as long as one is increased sputum purulence, and (3) patients requiring mechanical ventilation (noninvasive or invasive) regardless of symptoms (Table 45-22).[1] Utility of sputum Gram stain and culture is questionable, as some patients have chronic bacterial colonization of the bronchial tree between exacerbations.

C-reactive protein (CRP) has been evaluated as a potential biomarker to assist with decisions regarding the use of antimicrobial therapy for COPD exacerbations. An open-label randomized controlled trial evaluated the use of CRP measurement versus no CRP measurement when deciding whether to use antibiotics for AECOPD. The primary outcome was the percentage of antibiotic prescriptions issued within 4 weeks of initial exacerbation. Antibiotic prescriptions were issued less frequently when CRP levels were used to guide decisions compared to usual care. Moreover, patients in the CRP-guided group had improved COPD health status scores. The risk of hospitalization was similar in both groups. These results support the use of CRP measurements to guide antimicrobial decisions for AECOPD, and it supports antimicrobial stewardship efforts.[85]

The emergence of drug-resistant organisms has mandated that antibiotic regimens be chosen judiciously. The selection of empirical antimicrobial therapy should be based on the most likely organism(s) thought to be responsible for the infection based on the patient's presentation and site-specific sensitivities. The most common organisms for acute exacerbation of COPD are *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and *Haemophilus parainfluenzae*. More virulent bacteria may be present for patients with more complicated AECOPD, including drug-resistant pneumococci, β-lactamase–producing *H. influenzae* and *M. catarrhalis*, and enteric gram-negative organisms, including *Pseudomonas aeruginosa*. Table 45-23 summarizes recommended antimicrobial therapy for exacerbations of COPD and the most common organisms based on patient presentation. Therapy with antibiotics generally should be continued for at least 5 to 7 days. If the patient deteriorates or does not improve as anticipated, hospitalization may be necessary, and more aggressive attempts should be made to identify potential pathogens.

TABLE 45-23

Recommended Antimicrobial Therapy in Acute Exacerbations of COPD

Patient Characteristics	Likely Pathogens	Recommended Therapy
Uncomplicated exacerbations <4 exacerbations per year No comorbid illness	*S. pneumoniae* *H. influenzae* *M. catarrhalis* *H. parainfluenzae* Resistance uncommon	Macrolide (azithromycin, clarithromycin) Second- or third-generation cephalosporin Doxycycline Therapies not recommended[a]: TMP/SMX, amoxicillin, first-generation cephalosporins, and erythromycin
Complicated exacerbations Age ≥65 and >4 exacerbations per year Presence of comorbid illness	As above plus drug-resistant pneumococci, β-lactamase–producing *H. influenzae,* and *M. catarrhalis*	Amoxicillin/clavulanate Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, and moxifloxacin)
Presence of risk factors for colonization and infection with multidrug-resistant pathogens Need for chronic corticosteroid therapy Recent hospitalization (90 days) Recent antibiotic treatment (90 days) Resident of long-term care facility	Some enteric gram-negatives As above plus *P. aeruginosa*	Fluoroquinolone with enhanced pneumococcal and *P. aeruginosa* activity (levofloxacin) IV therapy if required: β-lactamase–resistant penicillin with antipseudomonal activity third- or fourth-generation cephalosporin with antipseudomonal activity

[a] TMP/SMX should not be used due to increasing pneumococcal resistance; amoxicillin and first-generation cephalosporins are not recommended due to β-lactamase susceptibility; erythromycin is not recommended due to insufficient activity against *H. influenzae.*

Controlled Oxygen Therapy

Oxygen therapy should be provided for patients with significant hypoxemia during an exacerbation (eg, oxygen saturation less than 90% [0.90]). Caution must be used, however, because many patients with COPD rely on mild hypoxemia to trigger their drive to breathe. In healthy individuals, drive to breathe is triggered by carbon dioxide accumulation. For patients with COPD who retain carbon dioxide due to disease progression, hypoxemia rather than hypercapnia becomes the main trigger for the respiratory drive. Overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. Oxygen therapy should be used to achieve a PaO_2 of greater than 60 mm Hg (8.0 kPa) or oxygen saturation of greater than 90% (0.90). An ABG should be obtained after oxygen initiation to monitor carbon dioxide retention resulting from hypoventilation.

Discharge Planning and Follow-up

Patients hospitalized for AECOPD are at high risk for relapse and readmission to the hospital; therefore, appropriate planning should take place prior to discharge to ensure therapy issues, and post-discharge care coordination are clearly addressed. Patients should be initiated or restarted on appropriate maintenance therapy (such as long-acting bronchodilators) before discharge. Patient assessment and education regarding new or continuing therapy should also occur before discharge and be reinforced during post-discharge follow-up. Some patients may require supplemental oxygen during their exacerbation and for a period of time after discharge. The continued need for long-term oxygen therapy should be assessed as part of post-discharge follow-up (Table 45-24). Other critical elements of discharge planning and follow-up include medication reconciliation, self-management plans, when to seek medical attention, assessment of symptoms and activities of daily living, and status of other comorbid conditions. Early follow-up after discharge (within 1-4 weeks) is associated with a reduction in readmission due to exacerbations of COPD, and lack of post-discharge follow-up is associated with an increase in 90-mortality.[1]

TABLE 45-24

Discharge Planning and Post-Discharge Follow-Up in Acute Exacerbations of COPD

Timeline	Assessment	Plans
Prior to discharge	Assess maintenance therapy and optimize per therapeutic goals and patient factors Assess inhaler technique Assess technique and adherence before modifying therapy Assess understanding of AECOPD medications (steroids and/or antibiotics) and when to stop taking after discharge Assess the need for vitamin D supplementation to prevent future exacerbations Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal) Assess need for oxygen therapy after discharge Assess needed follow-up for comorbid conditions	Ensure patient will be able to obtain and afford prescriptions for therapy Utilize motivational interviewing and teach-back for education and counseling Ensure understanding of medications to continue and/or stop (ie, antibiotics, systemic corticosteroids) Coordinate referral to outpatient tobacco cessation services, if indicated Provide immunizations while hospitalized Coordinate outpatient services for supplemental oxygen, if indicated Ensure follow-up care plans are communicated and appointments scheduled (ie, within 1-4 weeks post-discharge)
1-4 weeks post-discharge	Assess symptoms (ie, mMRC or CAT score) Assess patient ability to cope in their usual environment Assess physical activity and ability to do activities of daily living (ADLs) Assess inhaler technique Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal) Assess continued need for oxygen therapy, if continued after discharge Assess the status of comorbidities	Ensure patient completes mMRC or CAT before or during a visit Coordinate home care services for assistance with ADLs, if indicated Ensure patient will be able to obtain and afford prescriptions for therapy Utilize motivational interviewing and teach-back for education and counseling Ensure understanding of medications Coordinate referral to outpatient tobacco cessation services, if indicated Provide immunizations, if appropriate Coordinate outpatient services for supplemental oxygen, if indicated Ensure follow-up care plans are communicated and appointments scheduled
12-16 weeks post-discharge	Assess symptoms (ie, mMRC or CAT score) Assess patient ability to cope in their usual environment Assess physical activity and ability to do activities of daily	Ensure patient completes mMRC or CAT before or during a visit Coordinate home care services for assistance with ADLs, if

	living Assess airflow limitation via spirometry Assess inhaler technique Assess technique and adherence before modifying therapy Assess tobacco cessation readiness, if continued smoking Assess immunization status (influenza, pneumococcal) Assess continued need for oxygen therapy, if continued after discharge Assess the status of comorbidities	indicated Refer the patient for spirometry testing Ensure patient will be able to obtain and afford prescriptions for therapy Utilize motivational interviewing and teach-back for education and counseling Ensure understanding of medications Coordinate referral to outpatient tobacco cessation services, if indicated Provide immunizations, if appropriate Coordinate outpatient services for supplemental oxygen, if indicated Ensure follow-up care plans are communicated and appointments scheduled

It is important to assess medication understanding and potential barriers to adherence, inhaler technique, optimal pharmacotherapy, tobacco cessation readiness, and immunization status before discharge. In acute care or ambulatory care settings, clinical pharmacists are often called on to educate patients, recommend appropriate therapy changes, assist patients with formulary and insurance barriers, and complete prior authorization requests. The focus of COPD exacerbation management and prevention has shifted from only clinician-delivered education to patient-clinician collaboration that integrates motivation, engagement, and support to develop self-management interventions and target behaviors.[1,86] Key elements that should be addressed in self-management programs include risk factor management, inhaler technique, management of breathlessness, and a written action plan for acute exacerbations.[1] Incorporating an action plan for AECOPD within a self-management program has been shown to decrease respiratory-related hospital admissions and increase health-related quality of life indicators.[87] Dedicated programs targeting recently discharged patients have shown improvements in health outcomes, such as readmissions, when combined with clinical pharmacy services.[88–90]

PALLIATIVE CARE, END-OF-LIFE CARE, AND HOSPICE

Based on the natural course of COPD, characterized by a progressive decline in lung function and the development of complications, it is important to periodically reconsider the goals of care, end-of-life decisions, and advanced directives.[1] Involvement of palliative care services is recommended once symptoms become significantly limiting or disabling or if repeated hospitalizations occur. An effective strategy to discuss end-of-life care involves the patient's participation in identifying advanced directives and goals of care. Clinicians reassure patients that their symptoms, including pain, will be managed, and their dignity will be preserved. Specific issues that are addressed include the location and provider for terminal care, desire to use or withhold mechanical ventilation, and involvement of other family members in decisions on behalf of the patient.

EVALUATION OF THERAPEUTIC OUTCOMES

To evaluate therapeutic outcomes of COPD, the practitioner must first delineate between chronic stable COPD and acute exacerbations. In chronic stable COPD, pulmonary function tests should be annually assessed as recommended by guidelines and following any treatment additions or discontinuations. The average rate of decline of FEV_1 is a useful objective measure to assess the course of COPD over time. However, patients with similar FEV_1 values may differ in the frequency and severity of symptoms and exacerbation history, thus emphasizing the need for a combined assessment for all patients. The average rate of decline in FEV_1 for healthy, nonsmoking patients attributable to age alone is 25 to 30 mL/year. The rate of decline in smokers is steeper, especially for heavy smokers compared with light smokers. The decline in pulmonary function is a curvilinear path. The more severely diminished the FEV_1 at diagnosis, the steeper the rate of decline. Greater numbers of years of smoking and the number of cigarettes smoked correlate with a steeper decline in pulmonary function.[1]

Objective improvements in PFTs often are minimal—therefore, subjective assessments are important. These include symptom scores and quality-of-life assessments. In addition, exacerbation rates, visits to the emergency department, and hospitalizations should be quantified and evaluated. During AECOPD, the patient's white blood cell count, vital signs, chest x-ray, and changes dyspnea, sputum volume, and sputum purulence should be assessed at presentation and periodically throughout the treatment of an exacerbation. In severe exacerbations, ABGs and oxygen saturation also should be monitored. As with any drug therapy, adherence, adverse effects, and potential drug interactions should also be evaluated.

To date, there is limited evidence that any available pharmacotherapies for COPD impact disease progression. Removal of the primary causative factor for COPD (eg, cessation of cigarette smoking) does improve survival, as does supplemental oxygen therapy in a subset of patients. The most pertinent clinical outcomes that have emerged from clinical trials over the past decade are symptom improvement and reductions in exacerbation frequency. While it is important to continue to explore strategies to improve survival, consideration should be given to these two relevant and important outcome measures when initiating, continuing, and monitoring therapy.

SELF-ASSESSMENT QUESTIONS

1. Which of the following estimates of cigarette smoking as a cause of COPD is most accurate?

   A. 12%

   B. 30%

   C. 55%

   D. 75%

2. Which of the following is a risk associated with inhaled corticosteroid use for the treatment of COPD?

A. Increased mortality

B. Leukopenia

C. Osteoporosis

D. Pneumonia

3. Which of the following medication classes is utilized in the treatment of an acute exacerbation of COPD?

A. Short-acting beta-agonists

B. Long-acting beta-agonists

C. Inhaled corticosteroids

D. Long-acting muscarinic antagonists

4. Which of the following is an achievable outcome of pharmacotherapy for chronic management of COPD?

A. Reduced mortality

B. Normalization of spirometry

C. Reduced exacerbations

D. Prevention of accelerated loss of lung function

5. Which of the following pneumococcal vaccination strategies is recommended for a 59-year-old patient with COPD?

A. PPSV 23 only (pneumococcal polysaccharide)

B. PCV 13 only (pneumococcal conjugate)

C. PPSV 23 (pneumococcal polysaccharide) now, and PCV 13 (pneumococcal conjugate) in 8 weeks

D. PCV 13 (pneumococcal conjugate) now, and PPSV 23 (pneumococcal polysaccharide) in one year

6. Which of the following is a goal of supplemental oxygen therapy for chronic management of COPD?

A. Maintain pO_2 at normal levels

B. Reserve pCO_2 elevations

C. Prevent detrimental end-organ effects from hypoxemia

D. Increased hemoglobin concentrations

7. Which of the following counseling points is recommended for patients switching inhaled drug therapy from a metered-dose inhaler (MDI) to a dry powder inhaler (DPI)?

A. Continue to use an ancillary holding chamber with the new inhaler

B. There is no need to exhale before using the new inhaler

C. Use a rapid, forceful inhalation effort to aerosolize the dose of the new inhaler

D. Rinse the new inhaler in warm water daily to ensure consistent dose delivery

8. Which of the following genetic factors is a risk for developing COPD?

   A. Poor metabolizer status for cytochrome 3A4

   B. G6PD enzyme deficiency

   C. Atopic phenotype

   D. Alpha-1 antitrypsin deficiency

9. Which of the following best describes the impact of smoking cessation on the natural course of COPD?

   A. Cessation allows recovery of most of the excess loss of lung function.

   B. Following cessation, the rate of loss of lung function decreases to that of a nonsmoker.

   C. Significant increases in spirometry are evident within one year.

   D. The risk for lung cancer is similar to life-long nonsmokers following cessation.

10. Which of the following pharmacotherapy strategies is recommended for a patient newly diagnosed with Gold stage 1, category A COPD?

    A. Start an inhaled corticosteroid

    B. Start an inhaled bronchodilator

    C. Start an oral leukotriene modifier

    D. Start supplemental oxygen

11. Which of the following strategies is recommended for a COPD patient who currently smokes but is reluctant to attempt a cessation attempt because of the everyday stress in his life?

    A. Recommend bupropion therapy

    B. Recommend varenicline

    C. Recommend a nicotine replacement therapy and an anxiolytic agent

    D. Counsel about the relevance and rewards of smoking cessation

12. Which of the following therapies is appropriate to reduce the risk for exacerbations from COPD?

    A. Oral corticosteroids

    B. Long-acting muscarinic antagonists

    C. Antimicrobial agents

    D. Inhaled corticosteroids

13. Which of the following counseling points should be discussed with a patient who is starting roflumilast therapy?

    A. Do not use this medication with inhaled corticosteroids.

    B. This therapy should only be taken during periods of increased symptoms of exacerbation.

C. A common side effect of this medication is gastrointestinal, including nausea.

D. Take in divided doses at least twice daily.

14. Which of the following management strategies has been shown to reduce the progressive decline in lung function associated with COPD?

A. Smoking cessation

B. Inhaled corticosteroids

C. Long-acting beta-agonists

D. Supplemental oxygen therapy

15. Which of the following is recommended for a patient who continues to experience symptoms of COPD despite treatment with a single long-acting bronchodilator therapy?

A. Add a scheduled short-acting bronchodilator agent

B. Add an inhaled corticosteroid

C. Add another long-acting bronchodilator

D. Add a chronic anti-inflammatory such as azithromycin

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Cigarette smoking is implicated in approximately 75% of cases of COPD. However, less than 50% of smokers develop COPD. For more information, see the "Etiology" section.

2. **D.** There is good evidence regarding the association of inhaled corticosteroid use and an increased risk of pneumonia in patients with COPD. For more information, see subsection "Corticosteroids" under section "Pharmacologic Therapy."

3. **A.** When treating an acute exacerbation of COPD, intensification of short-acting bronchodilators and initiation of systemic corticosteroids and antimicrobials are primary strategies. For more information, see the "Exacerbation Management" section.

4. **C.** One of the most important goals of chronic COPD management is to prevent exacerbations that hasten disease progression. For more information, see subsection "Desired Outcomes" under section "Treatment."

5. **A.** PPSV 23 is recommended for patients under 65 years of age with COPD. For more information, see the "Immunizations" section.

6. **C.** A primary goal of supplemental oxygen is to maintain adequate oxygen concentrations in the blood to prevent detrimental effects on other organs. For more information, see the "Long-Term Oxygen Therapy" section.

7. **C.** When switching from an MDI to a DPI, the patient should be advised that the inhalation effort is different. A DPI requires a rapid, forceful inhalation effort. For more information, see section "Pharmacologic Therapy" as well as Chapter 44, "Asthma."

8. **D.** A deficiency of alpha-1 antitrypsin enzyme is associated with developing COPD (emphysema) at an early age. This enzyme usually has a protective role in lung tissue. For more information, see the "Etiology" section.

9. **B.** Upon cessation of smoking, the annual rate of FEV_1 loss is reduced to that of a nonsmoker. This provides potential years before the patient develops chronic symptoms associated with airflow limitation. For more information, see subsection "Smoking Cessation" under section "Nonpharmacologic Therapy and Health Maintenance Strategies."

10. **B.** The current GOLD guidelines recommend initial therapy with an inhaled bronchodilator for Group A patients without indicating any preference among agents. For more information, see subsection "Bronchodilators" under section "Pharmacologic Therapy," as well as Table 45-13.

11. **D.** In counseling individuals regarding tobacco cessation, it is essential to ensure readiness to quit before recommending pharmacotherapy. If the patient is not ready, ongoing counseling and encouragement are warranted. For more information, see subsection "Smoking Cessation" under section "Nonpharmacologic Therapy and Health Maintenance Strategies."

12. **B.** Long-acting bronchodilators (LAMA or LABA), either alone or in combination with each other, or ICS are the primary therapies shown to reduce exacerbation risks. For more information, see subsection "Bronchodilators" under section "Pharmacologic Therapy."

13. **C.** The most common side effects associated with roflumilast therapy are related to the gastrointestinal tract and include nausea. For more information, see subsection "Phosphodiesterase Inhibitors" under section "Pharmacologic Therapy."

14. **A.** Smoking cessation can impact the natural course of COPD and the progressive loss of lung function. To date, no pharmacotherapy has been shown to slow the loss of lung function. For more information, see subsection "Smoking Cessation" under section "Nonpharmacologic Therapy and Health Maintenance Strategies."

15. **C.** The central focus of COPD management is on bronchodilator therapy. If a patient is not adequately controlled with one agent, then combination bronchodilator therapy is recommended. Long-acting bronchodilators offer convenience as well as reducing exacerbation risks. For more information, see section "Pharmacologic Therapy."

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 46: Pulmonary Artery Hypertension

Rebecca L. Attridge; Rebecca Moote; Deborah J. Levine

KEY CONCEPTS

KEY CONCEPTS

① Pulmonary arterial hypertension (PAH) is defined as a mean pulmonary artery pressure (mPAP) ≥20 mm Hg at rest with a pulmonary capillary wedge pressure (PCWP) or left ventricular end-diastolic pressure ≤15 mm Hg and a pulmonary vascular resistance (PVR) >3 Wood units (24 MPa·s/m^3) measured by right heart cardiac catheterization.

② Patients with PAH most commonly present with exertional dyspnea, fatigue, weakness, and exercise intolerance. As the disease progresses, symptoms of right heart dysfunction and failure, such as dyspnea at rest, lower extremity edema, chest pain, and syncope, may be present.

③ The definitive diagnosis of PAH is done with a right heart catheterization. The right heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity prior to initiating therapy.

④ Treatment goals are to achieve low-risk status; alleviate symptoms; improve quality of life, functional class, and exercise capacity; slow disease progression; and improve survival.

⑤ Nonpharmacologic therapy, including counseling on pregnancy avoidance, structured pulmonary or cardiac rehabilitation, immunizations, and low-sodium diets, should be provided to all patients with PAH.

⑥ Conventional therapy options for PAH include oral anticoagulants, diuretics, oxygen, and digoxin.

⑦ Prostacyclin analogs such as epoprostenol, treprostinil, and iloprost induce potent vasodilation of pulmonary vascular beds. These therapies can be administered through different routes, including oral, inhaled, subcutaneous, and intravenous. Intravenous therapies are typically reserved for high-risk patients and are used in combination with endothelin receptor antagonists, phosphodiesterase-5 inhibitors, and riociguat. Only epoprostenol has demonstrated improved survival.

⑧ Oral combination therapy is recommended initially for patients with PAH at low-to-intermediate risk for mortality at 1 year. Options include endothelin-receptor antagonists, phosphodiesterase-5 inhibitors, riociguat, and selexipag. These agents improve exercise capacity, functional class, and hemodynamics in PAH.

⑨ Calcium channel blockers (CCBs) are only considered in a small number of patients who have a positive response to acute vasoreactivity testing. A small number of patients have a long-term response to CCBs.

BEYOND THE BOOK

BEYOND THE BOOK

The mechanism of action of medications used in pulmonary arterial hypertension (PAH) is directly tied to the pathophysiology of the disease. Create a concept map of the site of action of the major medication classes utilized in PAH—prostacyclin analogs, endothelin-receptor antagonists (ERAs), phosphodiesterase-5 inhibitors, and guanylate cyclase stimulators. This activity is intended to prepare you for understanding the role of the medications in the treatment of PAH as well as to increase critical thinking skills related to evaluating side effects and monitoring parameters of these medications.

INTRODUCTION

① Pulmonary arterial hypertension (PAH) is a group of conditions relating to elevated blood pressure measured within the pulmonary arteries. Pulmonary hypertension (PH) is not a specific diagnosis; rather it is a complex group of disorders relating to the pulmonary circulation. PH is classified into five groups according to the World Health Organization (WHO), see Table 46-1.[1] PAH, or Group 1 PH, is a progressive disease characterized by an elevation in pulmonary arterial pressure and pulmonary vascular resistance. PAH may be defined as a mean pulmonary artery pressure (mPAP) ≥20 mm Hg at rest, with a pulmonary capillary wedge pressure (PCWP) or left ventricular end-diastolic pressure ≤15 mm Hg and a pulmonary vascular resistance (PVR) >3 Wood units (24 MPa·s/m^3)measured by cardiac catheterization.[1–3]

TABLE 46-1

World Health Organization Classification of Pulmonary Hypertension

Group 1—Pulmonary Arterial Hypertension (PAH)

• Idiopathic (IPAH)
• Heritable
  ○ BMPR-2
  ○ Other mutations: ALK-1, ENG, SMAD9, CAV1, KCNK3
• Medications and toxin-induced PAH
• PAH associated with
  ○ Connective tissue diseases
  ○ HIV infection
  ○ Portal hypertension
  ○ Congenital heart diseases
  ○ Schistosomiasis
• PAH long-term responders to calcium channel blockers
• PAH with overt features of venous/capillaries (PVOD/PCH) involvement
• Persistent pulmonary hypertension (PH) of the newborn

Group 2—PH due to Left Heart Disease
• PH due to heart failure with preserved ejection fraction or heart failure with reduced ejection fraction • Valvular disease • Congenital/acquired cardiovascular conditions leading to post-capillary PH
Group 3—PH due to Lung Diseases and/or Hypoxia
• Obstructive pulmonary disease

- Restrictive lung disease
- Other lung diseases with a mixed restrictive and obstructive pattern
- Hypoxia without lung disease
- Developmental lung disorders

Group 4—PH due to pulmonary artery obstructions

- Chronic thromboembolic pulmonary hypertension (CTEPH)
- Other pulmonary artery obstructions
    - Sarcoma or angiosarcoma
    - Other intravascular tumors
    - Arteritis without connective tissue disease
    - Congenital pulmonary arteries stenosis
    - Parasites (hydatidosis)

Group 5—Pulmonary Hypertension with Unclear and/or Multifactorial Mechanisms

- Hematological disorders: chronic hemolytic anemia, myeloproliferative disorders
- Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, Gaucher disease, glycogen storage disease, neurofibromatosis
- Others: fibrosing mediastinitis, chronic renal failure (with/without dialysis)
- Complex congenital heart disease

ALK-1, activin receptor-like kinase type-1; BMPR-2, bone morphogenetic protein receptor 2; CAV1, caveolin-1; ENG, endoglin; EIF2AK4, eukaryotic translation initiation factor 2 alpha kinase 4; HIV, human immunodeficiency virus; PVOD, pulmonary veno-occlusive disease; PCH, pulmonary capillary hemangiomatosis.

Data from Reference 1.

PAH may occur in the setting of underlying medical conditions or as an idiopathic disease (idiopathic PAH [IPAH]). Historically, medical treatment of PAH has been limited due to lack of effective, targeted therapy. Without medical therapy, IPAH portends a poor prognosis (median survival 2.8 years) after diagnosis.[4] Prior to the availability of disease-specific therapy for IPAH, survival rates at 1, 3, and 5 years were 68%, 48%, and 34%, respectively.[5] Since the approval of epoprostenol in 1995, a number of new therapeutic options have been developed. Survival rates at 1 and 3 years were 85% and 68%, respectively, in patients with PAH, and 91% and 74%, respectively, in patients with IPAH.[6] Overall 5-year survival rates in that registry were 65% in previously diagnosed patients versus 61% in newly diagnosed patients with PAH.[7]

EPIDEMIOLOGY

The prevalence of PAH is 15 to 26 patients per million individuals.[8] One registry study found that the most common cause of PAH was IPAH (approximately 40%), followed by PAH associated with connective tissue diseases (15.3%), congenital heart disease (11.3%), portal hypertension (10.4%), and familial PAH (FPAH) (3.9%).[9] The US-based REVEAL (Registry to Evaluate Early and Long-Term Pulmonary Arterial Hypertension Disease Management) registry found that 46% of PAH was idiopathic, 25% was associated with connective tissue diseases, and 10% was associated with congenital heart diseases.[10] The incidence of IPAH is 2.0 to 7.6 per 1 million in North America and Europe, with a marked female predominance (male-to-female ratio, 1:1.7), and mean age at the time of recognition is approximately 37 years, although there is considerable variation.[11]

The diagnosis of PAH is growing due to increased awareness and knowledge of the disease state, leading to earlier and improved evaluation and identification. Based on recent registry data, PAH is now being diagnosed more commonly in older patients, with a mean age at diagnosis ranging from 50 to 65 years.[11]

ETIOLOGY

PAH most often originates with a predisposing state and one or more inciting factors that could be genetic or environmental exposures.[12] Once a permissive environment exists, multiple mechanisms can be activated leading to vascular constriction, cellular proliferation, and a prothrombotic state resulting in PAH and its sequelae.[13] PAH can be associated with numerous conditions as well as being an idiopathic condition (IPAH). Although uncommon in the United States, the most common form of PAH worldwide is schistosomiasis followed by congenital heart disease and pulmonary hypertension of early childhood.[2] Rheumatologic diseases such as scleroderma, systemic lupus erythematosus, rheumatoid arthritis, and myositis are also associated with the development of PAH. Patients with scleroderma who develop PAH, between 7% and 12% of patients, have markedly worse outcomes in comparison to other PAH subgroups. Patients with human immunodeficiency virus (HIV) infection can develop PAH with a prevalence of 0.5%. In patients with liver disease, portal hypertension may cause concurrent pulmonary hypertension in 2% to 6% of patients.[2] Multiple medications and toxins have been associated with PAH but those that definitively precipitate PAH include anorexigens such as aminorex, fenfluramine, benfluorex, and dexfenfluramine.[1,3,11] Other precipitants include toxic rapeseed oil and selective serotonin reuptake inhibitors (SSRIs), specifically in newborns of pregnant patients exposed to SSRIs after 20 weeks of gestation.[2,3] Other medications considered to be likely or possible causative agents for PAH include amphetamines, L-tryptophan, cocaine, interferon α and β, leflunomide, and certain chemotherapeutic agents (dasatanib, mitomycin C, carmustine, etoposide, cyclophosphamide, bleomycin).[1–3] Heritable PAH (HPAH) includes both IPAH with germline mutations and familial cases without an identified mutation. Germline mutations seen in PAH include bone morphogenetic protein receptor 2 (BMPR-2) and activin receptor-like kinase 1 (ALK-1). About 75% of patients with HPAH have BMPR-2 mutations.[14] Genetic testing for these mutations may be offered, and professional genetic counseling should be provided at expert centers.[2,14]

PATHOPHYSIOLOGY

PAH is characterized by progressive vasoconstriction of the small pulmonary arteries that eventually leads to right ventricular hypertrophy and failure. The right ventricle is thin-walled and accustomed to the much lower pressures of the pulmonary system and, therefore, does not have the reserve that the left ventricle does.[15] Regardless of etiology, all subgroups of PAH are based on similar clinical and pathologic physiology. The pathobiology of PAH involves several key biologic events, including endothelial cell dysfunction, thrombotic lesions, platelet activation, the gain of constricting factors, loss of relaxing factors, intimal proliferation, medial hypertrophy, fibrosis, and inflammation—all combining to produce progressive and deleterious vascular remodeling (FIGURE 46-1).[16,17] Multiple genetic mutations are known to contribute to the pathophysiology of PAH, including BMPR-2, ALK-1, Caveolin-1, KCNK3, nitric oxide synthase (ec-NOS), and 5-hydroxytryptamine (serotonin [5-HT]) transporter (5-HTT).[2,16,18]

Molecular, cellular, and genetic mechanisms are mediated by a variety of biologically active compounds, including prostacyclin (PGI_2), endothelin-1 (ET-1), nitric oxide (NO), and 5-HT. PGI_2 is a vasodilatory and antiproliferative substance that is produced by the endothelial cells. The synthesis of PGI_2 and its circulating levels is reduced in PAH. Furthermore, thromboxane, a vasoconstrictor, is increased in PAH. ET-1 is produced in the endothelium and possesses potent vasoconstrictor and mitogenic effects. ET-1 levels are increased in PAH, and clearance is reduced. ET-1 acts via the endothelin receptors (ET_A and ET_B) to promote vascular smooth muscle proliferation and vasoconstriction.[17,19] Plasma levels of ET-1 are correlated with the severity of PAH and prognosis.[20] NO is produced in the endothelium via NO synthase, leading to vasodilation. NO also leads to the opening of potassium channels in the cell membrane, allowing potassium efflux, membrane depolarization, and calcium channel inhibition. In PAH, there is evidence of decreased NO synthase expression, leading to vasoconstriction and cell proliferation.[21] Elevated 5-HT has been observed and vasoconstriction mediated via the increased expression of the $5\text{-}HT_{1B}$ receptor is seen in PAH.[2]

Autoantibodies, proinflammatory cytokines, and inflammatory infiltrates may also participate in the pathogenesis of PAH. Coagulation is disordered in PAH as evidenced by increased levels of von Willebrand factor, plasma fibrinopeptide A, plasminogen activator inhibitor-1, 5-HT, and thromboxane. Furthermore, tissue plasminogen activator, thrombomodulin, NO, and PGI_2 are decreased, leading to an imbalance favoring thrombosis. Endothelial dysfunction is the common denominator of mechanisms for PAH, and a variety of injuries, such as shear stress, inflammation, toxins, and hypoxia, are thought to be involved.[2,16]

CLINICAL PRESENTATION

② The signs and symptoms of PAH are highly variable depending on the stage of the disease and comorbidities. The impact of these signs and symptoms on functional capacity can be generally described using the WHO functional classification (Table 46-2). Symptoms are often related to right ventricular dysfunction and may include exertional dyspnea, fatigue, and weakness.[3] As the disease progresses, patients may experience dyspnea at rest, chest pain, presyncope, syncope, lower extremity edema, and abdominal bloating and distension. On physical examination, patients with PAH may have an accentuated component of S_2 audible at the apex of the heart, midsystolic ejection murmur, palpable left parasternal lift, right ventricular

S_4 gallop, and a prominent “a” wave.[2] Hepatojugular reflux, a diastolic murmur of pulmonary regurgitation, and a systolic murmur of tricuspid regurgitation may be present in advanced disease.[2] Patients with an increased risk of mortality are more likely to have a higher WHO functional class, older age, male gender, higher brain natriuretic peptide (BNP), higher right atrial pressure and lower cardiac output. In contrast, patients with a decreased risk of mortality are more likely to have a lower WHO functional class, higher 6-minute walking distance (6MWD), lower BNP, and higher cardiac output.[13]

TABLE 46-2

World Health Organization Functional Classification of Pulmonary Arterial Hypertension

Class	Description
I	Patients with PAH in whom there is no limitation of usual physical activity; ordinary physical activity does not cause increased dyspnea, fatigue, chest pain, or presyncope
II	Patients with PAH who have mild limitation of physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope
III	Patients with PAH who have marked limitation of physical activity. There is no discomfort at rest, but less than normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope
IV	Patients with PAH who are unable to perform any physical activity at rest and who may have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest, and symptoms are increased by almost any physical activity

Data from Reference 4.

③ Several comorbidities and environmental factors play a role in the development of PAH and must be evaluated when establishing an initial diagnosis of PAH (FIGURE 46-2). If PAH is suspected, a noninvasive screening test (eg, Doppler echocardiography) may detect increased pulmonary pressures. However, diagnosis of PAH requires additional testing.[22,23] Echocardiography is also useful in evaluating specific causes of pulmonary hypertension, such as a cardiac shunt or left-sided heart disease. Echocardiography can also be used to assess treatment interventions and to follow disease progression.[2] However, right heart catheterization is the definitive study to diagnose PAH and evaluate patients who are worsening clinically.[18]

Right heart catheterization is used to assess pulmonary vasoreactivity in patients with idiopathic, heritable, or medication-induced PAH. This test involves the administration of fast-acting vasodilators to determine the extent of vascular smooth muscle constriction and predict vasodilator response to calcium channel blockers (CCBs; class of recommendation I, level of evidence C).[4] Table 46-3 lists the classes of recommendations [COR] and levels of evidence [LOE], and Table 46-4 lists agents commonly used for vasoreactivity testing and their doses. The consensus definition of a positive vasoreactivity response is defined as a reduction of mPAP by at least 10 mm Hg to a value of 40 mm Hg or less with an unchanged or increased cardiac output.[24] Patients with a positive vasoreactivity response (approximately 13% of patients on initial testing) are most likely to have a beneficial hemodynamic and clinical response. These patients may be able to be treated with CCBs. However, about half of these patients lose an acute vasodilator response when tested 1 year later.[25] Therefore, even this small group of patients who may be treated with CCBs must be followed closely for safety and efficacy. If the patient loses the acute vasodilator response on follow-up assessment, they should be switched to different PAH therapy. Patients who have a negative response on initial vasodilator testing are not candidates for treatment with CCBs.[2,26]

TABLE 46-3

Classes of Recommendations and Levels of Evidence[a]

Classes of Recommendations (CORs)	Definition	Suggested Wording to Use
Class I	Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, effective.	Is recommended/Is indicated
Class II	Conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of the given treatment or procedure.	
Class IIa	Weight of evidence/opinion is in favor of usefulness/efficacy.	Should be considered
Class IIb	Usefulness/efficacy is less well established by evidence/opinion.	May be considered
Class III	Evidence or general agreement that a given treatment or procedures is not useful/effective, and in some cases may be harmful.	Is not recommended
Levels of Evidence (LOE)	**Definition**	
A	Data derived from multiple randomized clinical trials or meta-analyses.	
B	Data derived from a single randomized clinical trial or large nonrandomized studies.	
C	The consensus opinion of the experts and/or small studies, retrospective studies, registries.	

[a]Classes of Recommendations and Levels of Evidence are consistent between the ESC/ERS Guidelines and the WHO Guidelines.

Dosing increments	10-80 ppm for 5 minutes	2 ng/kg/min every 15 minutes	50 mcg/kg/min every 2 minutes
Common side effects	None	Headache, flushing, nausea	Chest tightness, dyspnea

Data from Reference 27.

Because PAH commonly occurs in the setting of connective tissue disease, serologic markers should be obtained to confirm or exclude these diagnoses.[2,28] Liver function tests (LFTs) should also be evaluated due to the increased risk for PAH in patients with cirrhosis and portal hypertension and as a baseline for certain PAH therapies. HIV is associated with an increased prevalence of PAH, and HIV testing should be done as part of the initial PAH workup.[2] CTEPH should be evaluated with ventilation-perfusion lung scans and/or pulmonary angiography. Pulmonary function testing and arterial blood oxygenation should be evaluated. The diffusing capacity of carbon monoxide may be particularly helpful in systemic sclerosis and PAH.[2]

In patients with PAH, serial determinations of functional class, exercise capacity (assessed by the 6MWD), and serial biomarkers (ie, BNP) provide benchmarks for disease severity, response to therapy, and progression.[2,28] These variables can be used to determine the risk level in patients and may aid in prognosis. Table 46-5 outlines the calculation of low-, intermediate-, and high-risk patients based on these factors, which is essential for determining initial therapy and assessing treatment response. Risk assessment tools continue to be developed and refined (such as REVEAL 2.0 and REVEAL Lite 2) to use the most predictive variables to assess risk while also simplifying the assessment to promote routine use in daily clinical practice.[29,30] Table 46-6 provides guidelines for initial and follow-up assessments and their timing.

TABLE 46-5

Risk Assessment in Pulmonary Arterial Hypertension

Determinants of Prognosis[a] (estimated 1-year mortality)	Low Risk <5%	Intermediate Risk 5%-10%	High Risk >10%
Clinical signs of right heart failure	Absent	Absent	Present

[a] Most of the proposed variables and cut-off values are based on expert opinion. They may provide prognostic information and are used to guide therapeutic decisions, but applications to individual patients must be done carefully. One must also note that most of these variables have been validated for IPAH and the cut-off values used above may not apply to other forms of PAH. Furthermore, the use of approved therapies and their influence on the variables should be considered in the evaluation of the risk.

[b] Occasional syncope during brisk or heavy exercise, or occasional orthostatic syncope in the otherwise stable patient.

[c] Repeated episodes of syncope, even with little or regular physical activity.

CLINICAL PRESENTATION: Pulmonary Arterial Hypertension

Symptoms

- Exertional dyspnea

- Fatigue
- Weakness
- Exertional chest pain
- Complaints of general exertion intolerance
- Dyspnea at rest as the disease progresses
- Syncope
- Lower extremity edema

Symptoms of Related Conditions

- Paroxysmal nocturnal dyspnea as a result of left-sided heart disease
- Raynaud's phenomenon, arthralgia, or swollen hands and other symptoms of connective tissue disease
- Orthopnea

Symptoms of Disease Progression

- Leg swelling
- Abdominal bloating and distension
- Anorexia
- Profound fatigue
- May develop as right ventricular dysfunction and tricuspid valve regurgitation evolve

Signs of Advanced Disease

- Diastolic murmur of pulmonary regurgitation
- A pansystolic murmur of tricuspid regurgitation
- Hepatojugular reflux
- Right ventricular S_3 gallop
- Marked distension of jugular veins
- Peripheral edema
- Hypotension
- Cool extremities suggesting markedly reduced cardiac output and peripheral vasoconstriction

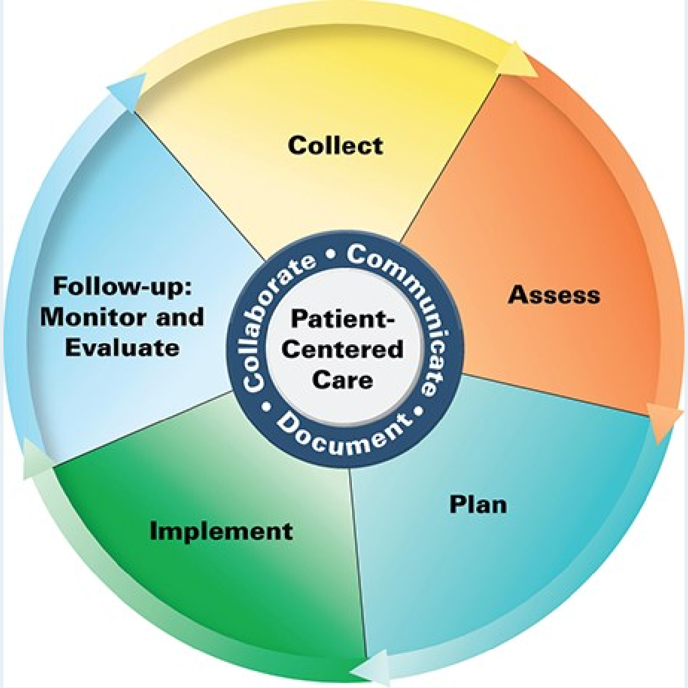
TREATMENT

Desired Outcomes

④ Specific goals in the treatment of PAH include lowering risk, improving quality of life and symptoms, and preventing disease progression and mortality.[13] Trials in the PAH population have undergone a change over the last decade. In the past, outcomes were predominantly focused on improvement in hemodynamic parameters and exercise tolerance.[31,32] However, more recent studies have focused on clinical outcomes, particularly combined clinical worsening. This outcome may differ among clinical trials but typically includes outcomes such as hospitalization, progression of symptoms, treatment escalation to prostacyclin therapy, transplantation, atrial septostomy, and death.[31]

PATIENT CARE PROCESS

Patient Care Process for Pulmonary Arterial Hypertension



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, gender, pregnancy status)
- Patient history: past medical (eg, connective tissue diseases), family (eg, family history of pulmonary arterial hypertension), social (eg, use of cocaine and amphetamines)
- Current medications (eg, particularly anorexigen use such as fenfluramine)
- Immunization history (eg, influenza, pneumococcal vaccination)
- Socioeconomic factors that may affect access to treatment
- Lifestyle assessment: smoking status, exercise, diet, alcohol intake, sexual activity
- Symptoms (eg, exertional dyspnea or chest pain, syncope, volume overload) and WHO Functional Class (Table 46-2)
- Objective data (Table 46-6)
  - Height, weight, BMI, blood pressure, and heart rate
  - Echocardiography and electrocardiogram

  - Right heart catheterization (with acute vasoreactivity testing if idiopathic, heritable, or anorexigen-associated PAH)
  - Labs (eg, AST/ALT, BNP)

Assess

- Rule out secondary causes (eg, left heart disease [Group 2], lung diseases and/or hypoxia [Group 3], CTEPH hypertension [Group 4], PH with unclear multifactorial mechanisms [Group 5])
- Assess groups with special considerations such as pregnant women
- Presence of comorbid conditions: atrial tachyarrhythmias, depression, anxiety, anemia
- Current medications that may affect PAH-targeted therapy (eg, drug–drug interactions)
- Recommended treatment options based on risk assessment (see FIGURE 46-3 and Table 46-5)
- Appropriateness and effectiveness of current PAH therapy (eg, current risk status [Table 46-5], WHO functional class [Table 46-2], exercise capacity, change in pulmonary pressures, if any)

Plan*

- Therapeutic lifestyle changes (eg, diet and nutrition)
- Medication therapy regimen including specific PAH medication, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Table 46-7)
- Evaluate current therapy for drug–drug interactions at each visit (see Table 46-9)
- Monitoring parameters including efficacy (eg, risk status [Table 46-5], WHO functional class [Table 46-2], exercise capacity, change in pulmonary pressures), safety (medication-specific adverse effects [Table 46-8]), and time frame (3-month initial follow-up intervals, followed by 6-12 month intervals once at goal) (see Table 46-6)
- Patient education (eg, the purpose of treatment, dietary and lifestyle modification, medication therapy, immunizations, counseling on pregnancy and air travel)
- Self-monitoring of weight, exercise, diet, medication adherence/adverse effects
- Referral to PAH specialty center for coordination of care

Implement*

- Provide patient education regarding all elements of the treatment plan
- For parenteral prostacyclin analogs, coordinate with specialty company to ensure appropriate education on agents, including reconstitution, safety, back-up supplies
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up and time frame to achieve goals of therapy (eg, low-risk status [Table 46-5], improvement in WHO functional class [Table 46-2] and exercise capacity, symptom improvement, euvolemia [see Table 46-6])
- Educate patient on when to seek medical care (eg, worsening edema or dyspnea)

Follow-up: Monitor and Evaluate

- Determine response to PAH therapy and volume management
- Presence of medication-induced adverse effects (eg, elevated transaminases on ERAs, headache, flushing, edema, pump issues with parenteral prostacyclin analogs [see Table 46-8])
- Routine pregnancy screening for females (especially if receiving ERAs or riociguat)
- The occurrence of PAH worsening (eg, worsening symptoms or hospitalizations for PAH)
- Patient adherence to the treatment plan

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

General Approach to Treatment

Treatment of PAH may be categorized into nonpharmacologic, pharmacologic, and surgical interventions. The principal pathophysiologic abnormalities that are current pharmacologic therapeutic targets include the following: (1) supplementing endogenous vasodilators, (2) inhibiting endogenous vasoconstrictors, and (3) reducing endothelial platelet interaction and limiting thrombosis. Nonpharmacologic therapy can be quite broad and should be used when clinically appropriate. Surgical therapy is indicated in certain situations and includes atrial septostomy, pulmonary thromboendarterectomy for CTEPH, and lung or heart-lung transplantation (for disease that is not responsive to medical therapy). Bilateral lung and lung-heart transplantation improves the survival rates in patients with PAH.[4]

Selection of targeted pharmacologic therapy should consider many factors, such as disease severity, safety profile, cost, and patient preference.[3] In 2019, the Sixth World Symposium on Pulmonary Hypertension published an updated series on PAH recommendations.[3] These guidelines recommend combination therapy as initial management for many patients with PAH, particularly WHO functional class II and higher. For patients on monotherapy with an inadequate response, an additional agent should be added to current therapy. Many patients with PAH will require combination therapy with two or three medications. Specific combination therapies will be discussed later on in this chapter.

Not all patients with PAH should be started on combination therapy. Those who are considered low risk may have improvement in symptoms with monotherapy. Other patient groups who may be candidates for monotherapy initially include those with multiple comorbidities, those at higher risk of adverse events, and populations of patients who were not included in the randomized controlled trials of initial combination therapy, such as patients with HIV or portal hypertension.[33]

Nonpharmacologic Therapy

⑤ Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH. Patients with PAH should be counseled on several important points. Pregnancy should be avoided due to high morbidity and mortality rates in females with PAH during pregnancy and in the postpartum course (COR I, LOE C).[3,4] Immunization against influenza and pneumococcal disease should be provided (COR I, LOE C).[3,4] Hypoxemia may aggravate pulmonary vasoconstriction in patients with PAH; therefore, patients with PAH may require supplemental oxygen (COR IIa, LOE C), particularly when using air travel.[4] Patients should adhere to a low-sodium diet to avoid fluid retention predisposing to right heart failure.[34] Counseling on smoking cessation should be provided to all patients who are active smokers. Cardiopulmonary rehabilitation improves functional status, exercise capacity, and quality of life in patients with PAH.[3]

Pharmacologic Therapy

The number of potential therapies for PAH has expanded dramatically in the last decade. In addition to adjunctive background therapy, multiple medications have been developed specifically for the treatment of PAH. FIGURE 46-3 illustrates the recommended treatment algorithm based on the most recent guidelines.[3,33]

FIGURE 46-3

Treatment algorithm. Conventional Pharmacologic Treatment

⑥ Conventional therapy includes oral anticoagulants, diuretics, oxygen, and digoxin.[33] Anticoagulation with warfarin may be considered on a case-by-case basis in patients with idiopathic, heritable, or drug-induced PAH (COR IIb, LOE C).[4] The rationale for oral anticoagulants is based on the presence of traditional risk factors for venous thromboembolism, such as heart failure and immobility, as well as thrombotic changes in the pulmonary microcirculation. Meta-analyses of small cohort studies demonstrate a 31% mortality risk reduction with anticoagulation.[35] However, recent observational studies report conflicting results regarding the benefit of anticoagulation in IPAH and associated PAH (APAH).[36,37] When warfarin is used, the target international normalized ratio (INR) in most centers is 1.5 to 2.5.[2,24] Anticoagulation is not recommended for patients with APAH due to HIV or portal hypertension.[33]

Loop diuretics such as furosemide are helpful adjunctive therapy in patients with decompensated right heart failure and associated findings of increased central venous pressure, abdominal organ congestion, peripheral edema, and ascites.[2] Appropriate diuretic therapy in right heart failure and volume overload provides symptomatic and clinical benefits in patients with PAH (COR I, LOE C).[4] Patients should be maintained at as close to a euvolemic state as possible.

Oxygen therapy with a goal oxygen saturation greater than 90% (0.90) may be beneficial in some patients with a PaO_2 <60 mm Hg (8.0 kPa), although no data exist regarding long-term benefit of oxygen treatment in PAH (COR I, LOE C).[4] Oxygen treatment is controversial in patients with PAH associated with shunts (ie, Eisenmenger's syndrome).

Digoxin may be used for patients with PAH with right heart failure as adjunctive therapy along with diuretics to control symptoms as well as in patients with atrial arrhythmias (COR I, LOE C).[4] There are no long-term trials, and clinical benefit is uncertain. Optimal plasma concentrations are unknown; however, based on data for digoxin use in heart failure with reduced ejection fraction, the typical target concentration is between 0.5 and 0.8 ng/mL (μg/L; 0.64 and 1 nmol/L). Patients on digoxin should receive periodic monitoring of potassium and renal function.

Lastly, iron-deficiency anemia is commonly reported in patients with PAH and may lead to decreased exercise capacity. Treatment of iron-deficiency anemia with iron replacement is recommended in patients with PAH (COR II, LOE b).[3,4] Anxiety and depression are frequent comorbidities in patients with PAH, occurring in up to 50%, with negative effects on perception of symptoms and quality of life. Appropriate counseling and treatment should be offered.[38]

Targeted Pharmacologic Therapy

The first medication, epoprostenol, developed to specifically target the disease process causing PAH was approved in 1995. Since then, there has been a surge in the availability of medication therapy for the treatment of PAH with five classes of medications now available. Specific pharmacologic therapy targets the disease process while conventional therapy is used for the management of symptoms and/or comorbid conditions.

Synthetic Prostacyclin and Prostacyclin Analogs

⑦ PGI_2 is produced predominantly by endothelial cells, inducing potent vasodilation of all vascular beds. It is also a potent inhibitor of platelet aggregation and possesses cytoprotective and antiproliferative activities. PGI_2 synthase expression is reduced in pulmonary arteries. Epoprostenol is a synthetic analog of PGI_2 and has a short half-life of 3 to 5 minutes; consequently, it must be given by continuous intravenous (IV) infusion. Initiation of epoprostenol should be done in a hospital setting at low doses ranging from 2 to 4 ng/kg/min and increased at a rate limited by side effects (flushing, headache, diarrhea, jaw pain, backache, abdominal cramping, extremity pain, and hypotension). During initiation and initial titration of epoprostenol, patients may require inotropic and/or blood pressure support for hemodynamic stability.[39] The two available products, Flolan® (generic formulation available) and Veletri®, have unique stability and reconstitution parameters; both pharmacists and patients should be aware of the differences and follow the manufacturer recommendations. Due to the short half-life of epoprostenol, it is recommended that the patient have backup supplies of both the medication and infusion pump, as interruption of therapy may lead to life-threatening pulmonary vasoconstriction.[40] Because the medication must be administered by continuous infusion with a central venous catheter and pump, bacteremia and catheter obstruction are potential complications. One study found that bloodstream infections occurred with epoprostenol and treprostinil in the range of 0.3 to 2.1 per 1,000 medicine days (approximately one infection every 3 years) when these medications are given IV.[41] The target dose for the first 2 to 4 weeks is around 10 to 15 ng/kg/min, and periodic dose increases are then required to maximize efficacy. Maintenance doses are variable but are often in the range of 25 to 80 ng/kg/min.[4] Multiple observational studies have documented an improvement in survival in patients with IPAH treated with epoprostenol.[4,42,43] Based on current guidelines, epoprostenol is indicated for WHO functional class III and IV (COR I, LOE A).[3,4]

Treprostinil is a stable analog of PGI_2 administered by subcutaneous (SC) or IV infusion and approved for WHO functional classes II, III, and IV.[44] The major advantages of treprostinil over epoprostenol include ease of use and increased safety due to a longer half-life. Because of the longer half-life, the risk of rebound vasoconstriction that may occur if therapy is interrupted is lower, resulting in an improved safety profile.[19] Treprostinil improves 6MWD and hemodynamics with outcomes that are similar to epoprostenol.[45,46] In clinical trials, the greatest exercise improvement was observed in patients who were more compromised at baseline and who could tolerate doses in the upper quartile (>13.8 ng/kg/min). The initial dose for treprostinil is 1.25 ng/kg/min by either the SC or IV route. If not tolerated, the dose should be reduced to 0.625 ng/kg/min and dose titration again attempted at 4 weeks. Infusion site pain is common with the SC route and can occur in up to 85% of patients, leading to discontinuation of treatment in 8% of patients and limiting upward dose titration.[4] Patients unable to tolerate SC can be transitioned to IV treprostinil.[24] Transitions between prostacyclin agents or routes should be performed in an inpatient setting at an expert referral center. Bloodstream infections, primarily due to gram-negative pathogens, are more likely with IV treprostinil than with IV epoprostenol.[47] The use of the diluent used for epoprostenol, which has a more basic pH, to reconstitute IV treprostinil may decrease rates of bloodstream infections to a rate similar to that seen with epoprostenol.[48] Other adverse drug reactions are similar to epoprostenol. Based on international guidelines, treprostinil is recommended for WHO functional class III (SC administration—COR I, LOE B; IV administration—COR IIa, LOE C) and functional class IV (SC and IV administration—COR IIb, LOE C).[3,4]

To prevent complications and use of pumps and central venous catheters for PGI_2 analog administration, aerosolized formulations were developed. The first approved formulation, iloprost (Ventavis), is a PGI_2 analog that is given by inhalation using a dosing system provided by the manufacturer (ADD system). The initial inhaled dose is 2.5 mcg 6 to 9 times per day up to every 2 hours during waking hours. The dose should be titrated and maintained at 5 mcg/dose if tolerated. In a 3-month clinical trial, iloprost via inhalation provided at least a 10% improvement in 6MWD and improvement in functional class.[49] Inhaled iloprost can be cumbersome to use as each inhalation dose can take 4 to 10 minutes to administer, and multiple inhalations are required for a full dose. Patients should also be instructed to have a backup supply as iloprost has a short half-life, similar to epoprostenol.[24] Adverse effects are similar to other PGI_2 analogs, including cough, headache, flushing, and jaw pain. Inhaled iloprost is indicated for functional class III (COR I, LOE B) and functional class IV (COR IIb, LOE C), although many clinicians prefer using PAH medications given via the IV or SC route in patients with more severe disease.[3]

The second aerosolized formulation, inhaled treprostinil, was approved by the Food and Drug Administration (FDA) in July 2009 to improve exercise capacity in functional class III patients. In a clinical trial, patients receiving inhaled treprostinil experienced a 20-mr improvement in 6MWD compared with those on placebo. All patients included in the trial were concurrently receiving bosentan or sildenafil for at least 3 months.[50] An open-label extension of the trial found that inhaled treprostinil provided sustained benefit and was safe and efficacious over a 2-year period.[51] The approved dosing of inhaled treprostinil is three breaths (18 mcg each) four times daily during waking hours. The dose may be titrated based on patient tolerance at 1- to 2-week intervals to a maximum dose of nine breaths four times daily. Inhaled treprostinil requires less time to administer, but the formulation is more complicated to prepare than inhaled iloprost.[24] While inhaled treprostinil avoids the infusion-related complications of the other PGI_2 analogs, use is cautioned in patients with acute pulmonary infections or underlying lung disease. The most common adverse effects seen in clinical trials include throat irritation, cough, headache, nausea, dizziness, and flushing. Inhaled treprostinil may also cause systemic hypotension, and patients should be monitored carefully if they are concurrently on diuretics, antihypertensives, or other vasodilators. Inhaled treprostinil is indicated for patients with WHO functional class III (COR I, LOE B) and IV (COR IIb, LOE C).[3,4]

Finally, the first oral prostacyclin analog, sustained-release treprostinil (Orenitram), was approved by the FDA in December 2013 for patients with WHO functional class II and III PAH. Oral treprostinil monotherapy for 12 weeks was associated with a significant increase of 23 m in 6MWD.[52] No differences were observed between treprostinil and placebo in time to clinical worsening or WHO functional class. Two randomized controlled trials followed evaluating the use of oral treprostinil in addition to ERAs and/or phosphodiesterase-5 inhibitors (PDE-5i). Neither study demonstrated a significant improvement in 6MWD with oral treprostinil therapy.[53,54] The average increase in 6MWD did correspond to treprostinil dose, with patients receiving higher doses demonstrating more improvement. Adverse events in studies included headache, nausea, diarrhea, and jaw pain; it is not well-tolerated overall, resulting in a high discontinuation rate of over 30%. Like other prostacyclin analogs, oral treprostinil inhibits platelet aggregation and may increase the risk of bleeding, especially in patients treated with anticoagulants. Oral treprostinil must be taken with food to improve absorption and cannot be crushed due to the osmotic release formulation. Oral treprostinil is indicated for patients with WHO functional class III (COR IIb, LOE B).[4]

Prostacyclin IP Receptor Agonist

Selexipag is a novel prostacyclin IP receptor agonist that was approved for use in patients with WHO functional class II and III PAH in 2015. Selexipag works by agonizing the prostacyclin IP receptor coupled with G_s protein, leading to increased cyclic adenosine monophosphate and relaxation of vascular smooth muscle. This leads to pulmonary vasodilation, as well as antiproliferative effects on smooth muscle cells and inhibition of platelet aggregation. The initial clinical trial evaluating the use of selexipag showed efficacy in decreasing pulmonary vascular resistance and improving cardiac index and 6MWD.[55] In a large clinical trial, patients with IPAH and APAH treated with selexipag experienced less disease progression, fewer hospitalizations for PAH, and reduced complications from PAH compared to placebo.[56] These outcomes were similar in patients on no background therapy and when added to background eERAs, PDE-5i, or both. This finding supports the use of triple oral combination therapy.[57] Similar benefits were seen with selexipag in a subgroup of patients with PAH associated with connective tissue diseases.[58] An additional substudy of this trial demonstrated that patients initiating therapy within 6 months of their PAH diagnosis demonstrated more pronounced reduction of morbidity and mortality with the addition of oral selexipag, further supporting oral combination therapy early in the disease.[59] Dose titration is similar to the prostacyclin analogs where the patient is initiated on a starting dose and titrated to the maximum tolerated dose. The initial starting dose is 200 mcg orally twice daily; this dose can be increased by 200 mcg twice daily increments to a maximum dose of 1,600 mcg twice daily. The median dose tolerated was 1,000 mcg twice daily in the clinical trial.[56] Patients with treatment interruptions greater than 3 days require re-titration of selexipag. Adverse drug reactions are common, especially during dose titration, and similar to those caused by prostacyclin analogs, including flushing, headache, diarrhea, nausea, jaw pain, and myalgias. Selexipag may also cause anemia; periodic monitoring of the complete blood cell count is warranted. Selexipag has also been associated with an increased incidence of hyperthyroidism. Current guidelines do not provide a recommendation on the role of selexipag in therapy.

Endothelin-Receptor Antagonists

⑧ ET-1, a peptide produced primarily by the vascular endothelial cells, is characterized as a powerful vasoconstrictor and mitogen for smooth muscle. Activation of the ET-1 system has been shown in both plasma and lung tissue of patients with PAH. There are three FDA-approved oral ERAs available for the treatment of PAH—bosentan, ambrisentan, and macitentan. All ERAs are orally administered and teratogenic. Patients must be enrolled in a Risk Evaluation and Mitigation Strategy (REMS) program for all ERAs. All ERAs can cause liver toxicity, although the incidence is highly variable across the class. ERAs are metabolized through cytochrome p450 (CYP) enzyme system and are, therefore, targets for drug-drug interactions, requiring providers to evaluate for potential drug-drug interactions.[44]

Ambrisentan is a once-daily selective ET_A receptor antagonist that improves exercise capacity and hemodynamics and delays clinical worsening in PAH.[60,61] Two large trials demonstrated a significant improvement in functional capacity with ambrisentan (at doses of 2.5, 5, and 10 mg daily) compared to placebo.[44,61] However, a greater response was seen with higher doses. All doses were well tolerated, and no patients on therapy experienced an increase in LFTs more than three times the upper limit of normal. Unlike bosentan, liver toxicity occurs rarely with ambrisentan (0.8% in 12-week trials and 2.8% for up to 1 year).[4] Common side effects include peripheral edema, nasal congestion, flushing, anemia, and palpitations. Treatment should be initiated with 5 mg once daily and increased to 10 mg once daily, if required. Ambrisentan is recommended for WHO functional class II and III (COR I, LOE A/B) as well as functional class IV (COR IIb, LOE C).[4]

Macitentan (Opsumit) is a once-daily dual ERA. In a phase III clinical trial, patients with PAH (primarily functional class II and III), including those on stable therapy with oral or inhaled prostanoids, CCBs, or oral PDE-5i, were randomized to macitentan 3 mg daily, 10 mg daily, or placebo.[62] Both macitentan doses demonstrated statistically significant decreases in composite events related to PAH or death compared to placebo, primarily due to less frequent worsening of PAH (defined as a decrease in 6MWD, worsening symptoms, and need for additional treatment). Increased LFTs occurred with similar frequency in all groups, about 3.5%-4.5%. More patients in the macitentan groups experienced nasopharyngitis, headache, and anemia than with placebo. The FDA-approved dose is 10 mg by mouth daily. Macitentan is recommended for WHO functional class II and III (COR I, LOE B) as well as functional class IV (COR IIb, LOE C).[4]

Bosentan is an orally active dual ET_A and ET_B receptor antagonist that improves exercise capacity, functional class, hemodynamics, echocardiographic and Doppler variables, and time to clinical worsening.[63–65] In one of the larger studies with bosentan, patients were started on 62.5 mg twice daily for 4 weeks followed by 125 or 250 mg twice daily for a minimum of 12 weeks. Both doses improved 6MWD, WHO functional class, and increased time to clinical worsening compared to placebo. Increases in hepatic aminotransferases occurred in 9% of patients and were dose-dependent.[64] The mechanism of increased liver enzymes is thought to be competition by bosentan and its metabolites with the biliary excretion of bile salts, resulting in the retention of bile salts that can be cytotoxic to hepatocytes. Because of this toxicity, bosentan is only available through a distribution program.[24] Bosentan should be started at 62.5 mg twice daily for 4 weeks. After 4 weeks of therapy, the dose should be increased to 125 mg twice daily. If LFTs are confirmed to be in the range of three to five times the upper limit of normal, reduce the daily dose or interrupt treatment. If LFTs return to pretreatment levels, bosentan may be continued or reintroduced if indicated. LFTs should be monitored at baseline and monthly thereafter. A complete blood count should be monitored every 3 months as bosentan has been associated with anemia. Bosentan is indicated for WHO functional class II and III (I-A/B) as well as functional class IV (COR IIb, LOE C).[1,4]

Phosphodiesterase Inhibitors

There are two PDE-5i available for the treatment of PAH—sildenafil and tadalafil. PDE-5i increase the intracellular concentration of cyclic guanosine monophosphate, leading to vasorelaxation and antiproliferative effects on vascular smooth muscle cells. PDE-5i commonly cause headaches and flushing as well as systemic hypotension. Both are contraindicated in combination with nitrates and riociguat due to increased risk of hypotension. Sildenafil and tadalafil both interact with bosentan, which is a potent CYP3A4 inducer.[66] Bosentan can decrease sildenafil and tadalafil concentrations by up to 50%, necessitating higher doses of PDE-5i when used in combination. PDE-5i are unique compared to other PAH therapies, as they are the only class that does not require enrollment in a REMS program nor acquisition through a specialty pharmacy.[62]

Sildenafil is a potent and highly specific PDE-5i that is approved for erectile dysfunction but also reduces mPAP and improves functional class. In one clinical trial, sildenafil added to conventional therapy significantly improved 6MWD and hemodynamic parameters at 12 weeks compared with placebo.[67] The FDA-approved dose is 20 mg orally three times per day; however, much higher doses are routinely used clinically. Common adverse drug reactions include headaches, flushing, epistaxis, dyspepsia, and diarrhea. Changes in vision have been reported, including blue-tinted vision and sudden loss of vision. In the event of sudden loss of vision, sildenafil should be stopped. Current guidelines recommend sildenafil for WHO functional class II and III patients with PAH (COR I, LOE A) in addition to functional class IV patients (COR IIb, LOE C).[4]

Another PDE-5i, tadalafil, was approved by the FDA in 2009 for the treatment of PAH. In a trial of patients with symptomatic PAH, more than 50% of whom were treated with bosentan at baseline, tadalafil 40 mg daily significantly improved exercise capacity, quality of life, and time to clinical worsening.[68] Treatment-naïve patients demonstrated not only greater improvement in exercise capacity than those on bosentan therapy but also greater improvement in all secondary outcomes. One possible explanation is decreased tadalafil levels as bosentan is a potent CYP3A4 inducer.[66] The most common adverse drug reactions were headache, myalgia, and flushing. Similar to sildenafil, tadalafil can also cause vision changes and dyspepsia. The recommended dose is 40 mg by mouth once a day.[68] Current guidelines recommend tadalafil for functional class II and III (COR I, LOE B) and functional class IV (COR IIb, LOE C).[4]

Guanylate Cyclase Stimulator

Riociguat is a soluble guanylate cyclase stimulator approved by the FDA in 2013. Riociguat works synergistically with nitric oxide and directly stimulates soluble guanylate cyclase. In a phase 3 study of patients with PAH, many of whom were on an ERA or non-IV prostacyclin analog at baseline, riociguat 2.5 mg by mouth three times daily improved 6MWD, hemodynamic parameters, and WHO functional class compared to placebo.[69] Syncope occurred in 1% of riociguat patients compared to 4% in the placebo group. The recommended starting dose is 1 mg orally, three times daily (TID), titrated by 0.5 mg TID every 2 weeks to a maximum dose of 2.5 mg by mouth TID. An initial starting dose of 0.5 mg TID may be used in patients with baseline hypotension. However, the use of riociguat is contraindicated in patients treated with PDE-5i due to the additive risk of hypotension. Riociguat is teratogenic and female patients must go through a REMS program to receive the medication. Smoking status should also be evaluated prior to initiation of riociguat because smoking reduces riociguat concentrations by 50% to 60%, potentially requiring dose adjustment to achieve the same effect. Riociguat is recommended for WHO functional class II and III (COR I, LOE B), functional class IV (COR IIb, LOE C), and is also approved for patients with Group 4 CTEPH.[4]

Calcium Channel Blockers

⑨ Since such a small number of patients with PAH have a positive response to acute vasodilator testing, CCBs are infrequently used. Approximately 13% of patients with IPAH will demonstrate an acute vasodilator response and may be initiated on CCB therapy. However, the number responding to long-term therapy is low (7%).[25] For the small group of patients that are long-term responders (at least 1 year on CCB monotherapy), a new clinical classification was added to the guidelines in group 1 PAH (Table 46-1).[1] Many long-term responders will lose the response to CCBs; therefore, patient response should be monitored closely with follow-up hemodynamic assessment with vasoreactivity testing. CCBs should not be used in the absence of demonstrated acute vasoreactivity.[3] If used in patients without acute vasoreactivity, CCBs are associated with systemic hypotension leading to reflex tachycardia, sympathetic stimulation, and right ventricular ischemia, ultimately increasing patient morbidity.[4] If used, dihydropyridine CCBs are preferred as they lack the negative inotropic effects seen with verapamil. Diltiazem may be used in patients who also have tachycardia to slow heart rate through atrioventricular node blockade. If left ventricular systolic dysfunction is present, diltiazem and verapamil should not be used. Assessment of CCB therapy should occur soon after initiation, and if improvement in functional class to class I or II is not seen, additional or alternative PAH therapy must be initiated. In acute responders, CCBs may be used in WHO functional classes I to IV (COR I, LOE C).[4] Compared to CCB doses used to treat other conditions (eg, hypertension), doses for PAH are relatively high—that is, up to 20 to 30 mg/day for amlodipine, 120 to 240 mg/day for nifedipine, and 240 to 720 mg/day for diltiazem. However, initial doses should be much lower and titrated upward to response.[4] The most common adverse drug reaction is peripheral edema. Specific information concerning individual medications used for PAH is shown in Tables 46-7–46-9.

TABLE 46-7

Dosing Recommendations for Common Treatments for Pulmonary Arterial Hypertension

Medication	Initial Dose	Usual Range	Other
Epoprostenol	2-4 ng/kg/min by IV infusion	Titrate up to 20-40 ng/kg/min	
Treprostinil (IV or SC)	1.25 ng/kg/min by continuous subcutaneous or IV infusion	Decrease to 0.625 ng/kg/min if not tolerated Increase by no more than 1.25 ng/kg/min weekly for the first 4 weeks of therapy and no more than 2.5 ng/kg/min weekly for the duration of therapy	
Treprostinil (inhaled)	Three inhalations (18 mcg) four times daily during waking hours (approximately 4 hours apart)	Reduce to one to two breaths if three breaths not tolerated; increase to three breaths when tolerance improves The goal maintenance dose is nine breaths (54 mcg) per treatment four times daily; titrate by increasing three breaths at 1- to 2-week intervals as tolerated	
Treprostinil (oral)	0.25 mg every 12 hours or 0.125 mg every 8 hours	Titrate dose in increments of 0.25-0.5 mg every 12 hours or 0.125 mg every 8 hours every 3- 4 days The maximum dose is determined by tolerability Avoid abrupt discontinuation; if not tolerated, decrease dose stepwise in 0.25-0.5 mg increments	If unable to continue oral therapy temporarily while inpatient, consider initiation of IV or SC treprostinil; 1/5 of the total daily oral dose is an estimate of total daily parenteral dose
Iloprost	2.5 mcg inhaled six to nine times daily (dosing at ≥2-hour intervals while awake)	Titrate to 5 mcg per dose with a maximum daily dose of 45 mcg	
Bosentan	62.5 mg orally twice daily	Increase to 125 mg orally twice daily	Available through Tracleer Access Program
Ambrisentan	5 mg orally daily	Titrate to maximum dose of 10 mg daily	Available through Letairis Education and Access Program

Macitentan	10 mg orally daily	Maximum dose of 10 mg orally daily	Available through Opsumit Risk Evaluation and Mitigation Strategy Program
Sildenafil	20 mg orally three times daily, taken at least 4-6 hours apart	Maximum FDA-approved dose is 20 mg orally three times a day; higher doses frequently used clinically	
Tadalafil	40 mg orally once daily, with or without food	40 mg orally once daily	Not recommended to divide the dose
Riociguat	0.5-1 mg orally three times daily	Maximum dose is 2.5 mg orally three times daily Titrate by 0.5 mg every 2 weeks to maximum tolerated dose; dose limited by hypotension	Use is contraindicated with PDE-5 inhibitors due to the risk of hypotension Available through Adempas Risk Evaluation and Mitigation Program
Selexipag	200 mcg orally twice daily	Titrate to maximally tolerated dose in 200 mcg increments; maximum dose 1,600 mcg orally twice daily	

IV, intravenous; SC, subcutaneous; FDA, Food and Drug Administration; PDE-5, phosphodiesterase-5.

TABLE 46-8

Monitoring Recommendations for Adverse Drug Reactions

Medication	Adverse Drug Reaction	Monitoring Parameter	Comments
Synthetic Prostacyclin and Prostacyclin Analogs			
Epoprostenol, Treprostinil (IV/SC/oral)	Pain (chest and jaw), flushing, headache	Patient reported symptoms	Occurs with dose titration; titrate to balance efficacy and adverse effect
	GI (nausea, vomiting, diarrhea, anorexia)	Patient reported symptoms	
	Hypotension	Blood pressure	Occurs with dose titration; additive hypotensive effects with other antihypertensives, vasodilators, and diuretics
	Thrombocytopenia	Platelets; signs and symptoms of bleeding	Monitor with concurrent anticoagulant and antiplatelet agents
Treprostinil (SC-specific)	SC site pain	Local pain at SC administration site	Frequent site rotation may improve; may also use cool compresses, lidocaine-based creams or patches, or pluronic lecithin organogel (PLO) to

			relieve pain
Treprostinil (inhaled)	Cough and throat irritation	Patient reported symptoms	
Iloprost	Cough and throat irritation	Patient reported symptoms	
Prostacyclin IP Receptor Agonist			
Selexipag	Pain (chest and jaw), flushing, headache	Titrate to balance efficacy and adverse effect	Occurs with dose titration
	GI (nausea, diarrhea)	Patient reported symptoms	
	Anemia	Hemoglobin	Monitor at baseline and then periodically throughout treatment
	Hyperthyroidism	Thyroid stimulating hormone	May monitor if associated symptoms
Endothelin-Receptor Antagonists			
Bosentan, Ambrisentan, Macitentan	Anemia	Hemoglobin	Usually resolves after the first 3 months of therapy
	Edema	Edema on physical exam	May require a dose increase of diuretic therapy
Bosentan (specific)	Hepatotoxicity	Baseline and monthly liver function tests required	Black box warning for liver injury
Phosphodiesterase-5 Inhibitors			
Sildenafil, Tadalafil	Headache	Patient reported symptoms; occurs due to vasodilation	
	Nasal congestion	Patient reported symptoms	
	Hypotension	Blood pressure	Concurrent use with nitrates potentiates effects
	Visual changes	Consider baseline exam; repeat exam if visual changes occur	
Soluble Guanylate Cyclase Stimulator			
Riociguat	Headache	Patient reported symptoms	
	Hypotension	Blood pressure	

	Peripheral edema	Edema on physical exam	
	Major bleeding	Hemoglobin and hematocrit Signs and symptoms of bleeding	
	Gastroesophageal reflux disease (GERD)	Patient reported symptoms; heart burn/reflux symptoms	

IV, intravenous; SC, subcutaneous; GI, gastrointestinal.

TABLE 46-9

Potentially Significant Drug Interactions with Pulmonary Arterial Hypertension Medications

PAH Medication	Mechanism of Interaction	Interacting Medication	Interaction
Ambrisentan	Unknown	Cyclosporine Ketoconazole	Caution is required in the coadministration of ambrisentan with ketoconazole and cyclosporine.
Bosentan	CYP3A4 inducer	Sildenafil	Sildenafil levels fall 50%; bosentan levels increase 50%. May not require dose adjustments of either medication.
	CYP3A4 substrate	Cyclosporine	Cyclosporine levels fall 50%; bosentan levels increase fourfold. Combination contraindicated.
	CYP3A4 substrate	Erythromycin	Bosentan levels increase. May not require dose adjustment of bosentan during a short course.
	CYP3A4 substrate	Ketoconazole	Bosentan levels increase twofold.
	CYP3A4 substrate + bile salt pump Inhibitor	Glibenclamide	Increase incidence of elevated aminotransferases. Potential decrease of hypoglycemic effect of glibenclamide. Combination contraindicated.
	CYP2C9 & CYP3A4 substrate	Fluconazole, amiodarone	Bosentan levels increase considerably. Combination contraindicated.
	CYP2C9 & CYP3A4 inducers	Rifampin, phenytoin	Bosentan levels decrease by 50%. Need for dose adjustment uncertain.
	CYP2C9 inducer	HMG CoA reductase inhibitors	Simvastatin levels reduce 50%; similar effects likely with atorvastatin. Cholesterol level should be monitored.
	CYP2C9 inducer	Warfarin	Increases warfarin metabolism, may need to adjust warfarin dose. Intensified monitoring of warfarin recommended following initiation but dose adjustment usually unnecessary.
	CYP2C9 & CYP3A4	Hormonal	Hormone levels decrease. Contraception unreliable.

	inducers	contraceptives	
Macitentan			Not yet determined.
Selexipag			Not yet determined.
Sildenafil[47]	CYP3A4 substrate	Bosentan	Sildenafil levels fall 50%; bosentan levels increase 50%. May not require dose adjustments of either medication.
	CYP3A4 substrate	HMG CoA reductase inhibitors (statins)	May increase simvastatin/atorvastatin levels through competition for metabolism, Sildenafil levels may increase. Possible increased risk of rhabdomyolysis.
	CYP3A4 substrate	HIV protease inhibitors	Ritonavir and saquinavir increase sildenafil levels markedly.
	CYP3A4 inducer	Phenytoin	Sildenafil levels may fall.
	CYP3A4 substrate	Erythromycin	Sildenafil levels increase. May not require dose adjustment for a short course.
	CYP3A4 substrate	Ketoconazole	Sildenafil levels increase. May not require dose adjustment.
	CYP3A4 substrate	Cimetidine	Sildenafil levels increase. May not require dose adjustment.
	cGMP	Nitrates, Nicorandil Molsidomine	Profound systemic hypotension, combination contraindicated.
Tadalafil[48]	CYP3A4 substrate	Bosentan	Tadalafil exposure decreases by 42%, no significant changes in bosentan levels.[48] May not require dose adjustment.
	cGMP	Nitrates, Nicorandil	Profound systemic hypotension, combination contraindicated.
Riociguat[18]	cGMP	Sildenafil, other PDE-5 inhibitors	Hypotension, severe side effects, combination contraindicated.
	cGMP	Nitrates, Nicorandil	Profound systemic hypotension, combination contraindicated.

HMG CoA, 3-hydroxy-3-methylglutaryl coenzyme A; HIV, human immunodeficiency virus; GMP, guanosine monophosphate.

Data from Reference 4.

Combination Therapy

10 Combination therapy is an attractive treatment option that targets multiple pathophysiologic mechanisms in PAH. This approach improves hemodynamics, symptoms, and exercise capacity. A significant portion of patients require combination therapy with either two- or three-drug regimens. Two meta-analyses found that combination therapy decreased time to clinical worsening by 35% to 40%.[32,70] Several trials have evaluated different combination therapies. The first-line recommended combination therapy in treatment-naive patients is an ERA with a PDE-5i. In a clinical trial

of patients with newly diagnosed PAH, initial combination therapy with ambrisentan and tadalafil was associated with a significant reduction in time to clinical failure and PAH hospitalizations compared to either therapy alone.[71] Peripheral edema, headache, nasal congestion, and anemia were more common in the combination group than either monotherapy group. However, there was no difference in medication discontinuation due to adverse events.[71] This initial combination is considered a class I recommendation (LOE B) for WHO functional class II and III patients and a class IIb recommendation (LOE C) for WHO functional class IV patients.[4]

While not specifically evaluated as initial combination therapy, the addition of macitentan to a PDE-5i or nonparenteral prostanoid therapy delayed clinical worsening in one trial.[72] Another study found a 40% decrease in clinical worsening when selexipag was added to background therapy; clinical improvements were similar regardless of the type of background therapy (ERA, PDE-5i, or a combination).[73] In a post hoc analysis, investigators found a more profound effect in patients who were started on selexipag within 6 months of diagnosis.[74] Sildenafil added to epoprostenol provided significant improvements in clinical outcomes and delay in clinical worsening.[75] Riociguat combined with ERAs showed benefit at 12 weeks.[69]

Current guidelines state the combination therapies with the strongest evidence and guideline support include the following: macitentan and sildenafil, riociguat and bosentan, and selexipag and ERA and/or PDE-5i.[33] A recent study compared an initial triple therapy (macitentan, tadalafil, and selexipag) to initial dual therapy (macitentan and tadalafil) in patients with PAH and found no difference in pulmonary vascular resistance but reduced the risk of disease progression with initial triple therapy.[76] Adverse drug reactions occurring more frequently in the triple therapy group included headache, diarrhea, nausea, pain in extremity, jaw pain, and vomiting.[76]

Tables 45-10 and 45-11 show current treatment recommendations for initial combination and sequential combination therapy, respectively.

TABLE 46-10

Recommendations for Efficacy of Initial Medication Combination Therapy for Pulmonary Arterial Hypertension (group 1) According to World Health Organization Functional Class

Treatment	Class of Recommendations/Level of Evidence					
	WHO-FC II		WHO-FC III		WHO-FC IV	
Ambrisentan + tadalafil[a]	I	B	I	B	IIb	C
Other ERA + PDE-5i	IIa	C	IIa	C	IIb	C
Bosentan + sildenafil + iv epoprostenol	-	-	IIa	C	IIa	C
Bosentan + iv epoprostenol	-	-	IIa	C	IIa	C
Other ERA or PDE-5i + sc treprostinil			IIb	C	IIb	C
Other ERA or PDE-5i + other iv prostacyclin analogs			IIb	C	IIb	C

ERA, endothelin-receptor antagonist; iv, intravenous; PDE-5i, phosphodiesterase type 5 inhibitor; RCT, randomized controlled trial; sc, subcutaneous; WHO-FC, World Health Organization functional class.

[a] Time to clinical failure as primary endpoint in RCTs or medications with demonstrated reduction in all-cause mortality (prospectively defined).

TABLE 46-11

Recommendations for Efficacy of Sequential Medication Combination Therapy for Pulmonary Arterial Hypertension (group 1) According to World Health Organization Functional Class.

Treatment	Class of Recommendation / Level of Evidence					
	WHO-FC II		WHO-FC III		WHO-FC IV	
Macitentan added to sildenafil[a]	I	B	I	B	IIa	C
Riociguat added to bosentan	I	B	I	B	IIa	C
Selexipag added to ERA[b] and/or PDE-5i[a]	I	B	I	B	IIa	C
Sildenafil added to epoprostenol	-	-	I	B	IIa	B
Treprostinil inhaled added to sildenafil or bosentan	IIa	B	IIa	B	IIa	C
Iloprost inhaled added to bosentan	IIb	B	IIb	B	IIb	C
Tadalafil added to bosentan	IIa	C	IIa	C	IIa	C
Ambrisentan added to sildenafil	IIb	C	IIb	C	IIb	C
Bosentan added to epoprostenol	-	-	IIb	C	IIb	C
Bosentan added to sildenafil	IIb	C	IIb	C	IIb	C
Sildenafil added to bosentan	IIb	C	IIb	C	IIb	C
Other double combinations	IIb	C	IIb	C	IIb	C
Other triple combinations	IIb	C	IIb	C	IIb	C
Riociguat added to sildenafil or other PDE-5i	III	B	III	B	III	B

EMA, European Medicines Agendy; ERA, endothelin-receptor antagonist; PAH, pulmonary arterial hypertension; PDE-5i, phosphodiesterase type 5 inhibitor; RCT, randomized controlled trial; WHO-FC, World Health Organization functional class.

[a] Time to clinical failure as primary endpoint in RCTs or medications with demonstrated reduction in all-cause mortality (prospectively defined).

[b] This medication was not approved by the EMA at the time of publication of these guidelines.

Fusion Protein

An emerging treatment option in development is sotatercept. Sotatercept is a fusion protein composed of the extracellular domain of the human activin receptor type IIA linked to the Fc domain of human IgG1.[77] Sotatercept impairs activation in the transforming growth factor ß (TGF-ß) pathway, thereby restoring the balance between proproliferative and antiproliferative pathways. Mutations in the TGF-ß pathway, specifically BMPR2, are present in 70% to 80% of heritable PAH and in 10% to 20% of IPAH.[14] In a phase 2 trial, sotatercept dosed at 0.3 mg/kg or 0.7 mg/kg SC every 3 weeks reduced pulmonary vascular resistance at 24 weeks in patients with PAH on background therapy, the majority of whom were on double or triple therapy while many others were on intravenous prostacyclin therapy.[77] Thrombocytopenia occurred in 6% of the lower dose group and 12% in the higher dose. An increase in hemoglobin was also seen in 3% of patients on the lower dose and 17% of patients on higher dose, perhaps because the TGF-ß pathway is involved in hematopoiesis. In 2020, the FDA granted Breakthrough Therapy status for sotatercept for the treatment of PAH, and phase 3 trials are ongoing.

Special Populations

Pregnancy

Pregnancy confers an increased risk of mortality in patients with PAH. Guidelines recommend encouraging patients with PAH to actively avoid pregnancy.[4] There is no consensus on the best birth control method for patients with PAH, but the use of two methods should be considered. Estrogen-containing products should be avoided. Patients who do become pregnant need to be referred as soon as possible to a PH center where there are expert high-risk obstetricians and PAH specialists who have experience in this area.[4] All ERAs (bosentan, ambrisentan, and macitentan) are teratogenic, as is riociguat. These medications should be discontinued immediately if a patient becomes pregnant and therapy needs to be adjusted. Monthly pregnancy tests are required for use of ERAs and riociguat. It is also important to note that bosentan may decrease the efficacy of oral birth control medications (Table 46-9).

Evaluation of Therapeutic Outcomes

All patients with PAH, regardless of risk status, should be reevaluated within 3 to 6 months of starting therapy.[33] Current guidelines recommend the use of a comprehensive risk assessment tool to assess prognosis and inform therapy (Table 46-5). Additionally, recent studies have reported successful use of refined risk assessment tools that use the most predictive variables and simplify assessment for clinicians.[29,30] If a patient has achieved a low-risk status, therapy should be continued. If a patient is considered intermediate risk, additional therapy should be considered. This may result in initial combination therapy escalating to triple therapy in some patients. Patients who are high risk on follow-up should be initiated on IV prostacyclin therapy and referred for lung transplant evaluation. Table 46-6 provides recommendations regarding specific baseline and follow-up assessments and when they should be performed.

CONCLUSION

PAH is an uncommon disease state with complex therapies. Significant advances have been made in elucidating the pathogenesis of PAH as well as in the evaluation and treatment of these patients over the past three decades. With targeted therapies such as ERAs, PDE-5i, and PGI_2 analogs, clinical improvement is possible in most patients, leading to a higher quality of life and delayed disease progression. Patient education is important to improve acceptance of this disease and referral to specialty care centers may provide the best outcomes.

ABBREVIATIONS

6MWD	6-minute walking distance
5-HT	serotonin
5-HTT	5-hydroxytryptamine transporter
ALK-1	activin receptor-like kinase 1
APAH	associated pulmonary arterial hypertension
BMPR-2	bone morphogenetic protein receptor 2

BNP	brain natriuretic peptide
CCB	calcium channel blocker
COR	class of recommendation
CTEPH	chronic thromboembolic pulmonary hypertension
CYP	cytochrome p450
ERA	endothelin-receptor antagonist
ET-1	endothelin-1
FDA	Food and Drug Administration
HIV	human immunodeficiency virus
HPAH	heritable pulmonary arterial hypertension
INR	international normalized ratio
IPAH	idiopathic pulmonary arterial hypertension
IV	intravenous
LOE	level of evidence
LFT	liver function test
NO	nitric oxide
NOS	nitric oxide synthase
PAH	pulmonary arterial hypertension
PAP	pulmonary artery pressure
PCWP	pulmonary capillary wedge pressure
PDE-5i	phosphodiesterase-5 inhibitors
PGI2	prostacyclin
REMS	Risk Evaluation and Mitigation Strategy
SC	subcutaneous
SSRIs	selective serotonin reuptake inhibitors
TGF-β	transforming growth factor-β

SELF-ASSESSMENT QUESTIONS

1. Pulmonary hypertension can be defined as a mean pulmonary artery pressure of ≥____ mm Hg at rest with a pulmonary capillary wedge pressure equal to or less than 15 mm Hg measured by right heart catheterization.

   A. 10

   B. 15

   C. 20

   D. 25

2. Which of the following symptoms is *not* suggestive of pulmonary arterial hypertension?

   A. Exertional chest pain

   B. Syncope

   C. Lower extremity edema

   D. Wheezing

3. Which of the following pathophysiologic abnormalities is a target of current pharmacologic treatments for PAH?

   A. Supplementing endogenous vasodilators

   B. Increasing endothelial platelet interaction and limiting thrombosis

   C. Reducing levels of serotonin

   D. Supplementing endogenous vasoconstrictors

4. Patients who are unresponsive to acute vasoreactivity testing are *not* candidates for which class of medication therapy?

   A. Calcium channel blockers

   B. Endothelin antagonists

   C. Phosphodiesterase inhibitors

   D. Prostacyclin analogs

5. A 34-year-old female presents to your clinic with increasing dyspnea with mild exertion for 2 years, chest tightness, occasional ankle edema, and a recent episode of near syncope. The patient denies paroxysmal nocturnal dyspnea, orthopnea, wheezing, or palpitations but does report a 15-lb (6.8 kg) weight gain over the last year. Past medical history includes having two children without pregnancy complications. The patient has no known medication allergies and is not currently taking any medications. Family history is significant for type 2 diabetes mellitus. Physical examination: The patient is 5 ft 5 in. (165 cm) and 180 lb (81.6 kg) with a body mass index of 30 kg/m^2. Heart rate is 86 beats/minute with a blood pressure of 128/74 mm Hg.

   Significant findings: Jugular venous pressure is 12 cm. Normal S_1 and S_2, 3/6 tricuspid murmur; 1+ lower extremity edema.

   Imaging: Chest x-ray and electrocardiogram are ordered.

   On the basis of the clinical presentation, what diagnostic test would be the most appropriate to order now?

   A. Pulmonary angiography

   B. Echocardiography

   C. Doppler ultrasound of lower extremity

   D. Coronary angiography

6. Which of the following medications is associated with significant elevations in aminotransferases, requiring baseline and monthly monitoring?

   A. Epoprostenol

   B. Amlodipine

   C. Sildenafil

   D. Bosentan

7. A patient presenting with no discomfort at rest but increased dyspnea, fatigue, and chest pain on mild physical exertion is classified in which World Health Organization functional class?

   A. Class I

   B. Class II

   C. Class III

   D. Class IV

Use the following case to answer questions 8 and 9:

A 28-year-old female presents to your clinic with increasing dyspnea with mild exertion for 1 year, chest tightness, and occasional ankle edema, consistent with World Health Organization Class II pulmonary arterial hypertension. The patient denies paroxysmal nocturnal dyspnea, orthopnea, wheezing, or palpitations but does report an 8-lb (3.6 kg) weight gain over the last year. The patient has no known drug allergies and is not currently taking any medications. The patient has previously been found unresponsive to acute vasoreactivity testing and is currently low-risk status.

8. What is the *most* appropriate initial treatment for this patient?

   A. Sildenafil 100 mg orally daily

   B. Epoprostenol 2 ng/kg/min continuous infusion

   C. Ambrisentan 5 mg orally daily and tadalafil 40 mg orally daily

   D. Amlodipine 5 mg orally daily

9. Which of the following drugs should this patient avoid?

   A. Ibuprofen

   B. Digoxin

   C. Furosemide

   D. Acetaminophen

10. Which of the following agents is *not* used for acute vasoreactivity testing in pulmonary arterial hypertension?

   A. Epoprostenol

   B. Nitroglycerin

   C. Adenosine

   D. Nitric oxide

11. Which of the following best describes the mechanism of action of epoprostenol?

   A. A competitive antagonist of endothelin receptors, causing vasodilation of the pulmonary vasculature

   B. Phosphodiesterase inhibition, causing an increase in cyclic guanosine monophosphate leading to vasorelaxation

C. Inhibition of influx of extracellular calcium, leading to vasodilation

D. Direct vasodilation of pulmonary vascular beds as well as inhibition of platelet aggregation

12. Infection, catheter obstruction, and sepsis are potentially serious complications of which of the following medications?

    A. Bosentan

    B. Sildenafil

    C. Treprostinil

    D. Diltiazem

13. TP is a 68-year-old female with PAH. The patient describes worsening symptoms lately. The patient used to be able to walk the dog around the block but is no longer able to do so without feeling exhausted. The patient feels shortness of breath and fatigue even when resting in a recliner. Upon assessment, the patient is categorized as high risk and is currently treated with sildenafil 40 mg orally three times daily. Which agent is most appropriate to add now?

    A. Epoprostenol

    B. Ambrisentan

    C. Riociguat

    D. Selexipag

14. Women of child-bearing age with pulmonary arterial hypertension should be counseled on the risks of pregnancy. Which of the following medications is teratogenic in pregnancy?

    A. Macitentan

    B. Amlodipine

    C. Epoprostenol

    D. Selexipag

15. Epoprostenol is indicated for patients with PAH in which of the following WHO functional classifications?

    A. WHO functional class I and II

    B. WHO functional class II and III

    C. WHO functional class II, III, and IV

    D. WHO functional class III and IV

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Current guidelines defined pulmonary arterial hypertension as mean pulmonary artery pressure of ≥20 mm Hg at rest with a pulmonary capillary wedge pressure equal to or less than 15 mm Hg measured by right heart catheterization. See the "Introduction" section for more information.

2. **D.** Exertional dyspnea, chest pain, and lower extremity edema are all common symptoms of pulmonary arterial hypertension. Wheezing is not a characteristic symptom and is more common with obstructive lung diseases, such as asthma or chronic obstructive pulmonary disease. See the "Clinical Presentation" box for more information.

3. **C.** Reducing levels of serotonin is not a current target of pharmacologic treatment for PAH. Multiple medication classes either target supplementing endogenous vasodilators or inhibiting endogenous vasoconstrictors. Prostacyclin analogs and selexipag are examples of medication classes that supplement endogenous vasodilators and reduce endothelial platelet aggregation, while endothelin-receptor antagonists are an example of agents that inhibit endogenous vasoconstrictors. See the "Pharmacologic Therapy" section for more information.

4. **A.** Patients who have a negative acute vasoreactivity test should not receive therapy with a calcium channel blocker. The use of calcium channel blockers in patients with a negative acute vasoreactivity test on right heart catheterization may lead to increased patient morbidity. See "Calcium Channel Blockers" section for more information.

5. **B.** Echocardiography is the most commonly used assessment for initial screening of patients who may have pulmonary arterial hypertension. Echocardiography is useful because it is less invasive than right heart catheterization (which will still be required for definitive diagnosis) and may also rule out other causes.

6. **D.** Bosentan is the most likely medication to cause elevations in transaminases. Bosentan has a US-boxed warning requiring practitioners to monitor liver function tests at baseline and monthly thereafter in all patients on therapy. Elevated transaminases and hepatotoxicity are not as likely with the other endothelin-receptor antagonists (ambrisentan and macitentan) so they do not carry the same warning. See Table 46-8 for more information.

7. **B.** This patient shows symptoms on mild exertion but no discomfort at rest, which is characteristic of WHO functional class II. See Table 46-2 for more information.

8. **C.** The most appropriate therapy to initiate this patient is on oral combination therapy with ambrisentan 5 mg po daily and tadalafil 40 mg orally daily. Amlodipine is not appropriate because the patient had negative acute vasoreactivity test. While sildenafil is an appropriate agent, the dose is too high and not at the appropriate frequency; the normal starting dose of sildenafil is 20 mg PO TID. In addition, initial oral combination therapy is now recommended in low and intermediate risk patients. Lastly, epoprostenol and other prostacyclin analogs are reserved for high-risk patients. See Table 46-7 and FIGURE 46-3 for more information.

9. **A.** Ibuprofen and other NSAIDs should be avoided in patients with PAH due to worsening edema and heart failure.

10. **B.** Nitroglycerin is not used for acute vasoreactivity testing in pulmonary arterial hypertension. See Table 46-4 for more detailed information on the other three agents that are indicated for acute vasoreactivity testing.

11. **D.** Epoprostenol is a prostacyclin agent that causes direct vasodilation to pulmonary vascular beds. See "Synthetic Prostacyclin and Prostacyclin Analogs" section for more information. Endothelin-receptor antagonists such as bosentan, ambrisentan, and macitentan are competitive antagonists of endothelin receptors. Sildenafil and tadalafil inhibit phosphodiesterase-5, while calcium channel blockers inhibit the influx of extracellular calcium.

12. **C.** Infection, catheter obstruction, and sepsis are potentially serious complications of the parenteral prostacyclin agents, including treprostinil and epoprostenol. See "Synthetic Prostacyclin and Prostacyclin Analogs" section for more information.

13. **A.** The patient is currently high risk and on sildenafil treatment. The most appropriate therapy to add is a parenteral prostacyclin analog like epoprostenol. Sildenafil and riociguat are contraindicated in combination due to additive risk of hypotension. See FIGURE 46-3 and Table 46-11 for more information on double and sequential treatment in patients already on therapy.

14. **A.** The endothelin-receptor antagonists, such as macitentan, and the soluble guanylate cyclase stimulator, such as riociguat, are teratogenic and contraindicated in pregnancy.

15. **D.** Epoprostenol is reserved for high-risk patients with more severe functional classes, including WHO functional class III and IV. See "Synthetic Prostacyclin and Prostacyclin Analogs" section and FIGURE 46-3 for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 47: Cystic Fibrosis

Kim G. Adcock; Ha Phan; David Josey, Jr.

KEY CONCEPTS

KEY CONCEPTS

① Cystic fibrosis (CF) is caused by a functional loss of the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This leads to reduced chloride and bicarbonate secretion and a buildup of thick mucus throughout the body affecting the lungs, pancreas, liver, intestine, and reproductive tract. Thus, CF is a multisystem disease with most patients experiencing a wide range of symptoms and diverse organ complications.

② Three classes of CFTR modulators play an important role in the treatment of CF. Although there is no cure for CF, the CFTR modulator class of medications alleviates and corrects the underlying pathophysiology.

③ Infection is one of the main causes of morbidity and mortality in patients with CF and contributes to CF lung disease. Treating infections in CF involves not only antibiotics but chest physiotherapy and inhaled mucolytics play an important adjunction role. Strategies should be employed to prevent *Pseudomonas aeruginosa* acquisition including measures to prevent transmission between CF patients and early eradication of both *P. aeruginosa* and *Staphylococcus aureus* with appropriate treatment regimens. Chronic colonization with *P. aeruginosa* necessitates chronic treatment with inhaled antibiotics.

④ Pancreatic exocrine insufficiency occurs in CF patients as a result of pancreatic duct obstruction. If left untreated, pancreatic insufficiency leads to growth failure, weight loss, abdominal bloating, foul-smelling stools, or diarrhea. Pancreatic enzyme replacement therapy is the treatment of choice.

⑤ Dosing of antibiotics in CF patients can be a challenge to ensure adequate lung penetration and maximum bactericidal activity. In addition, the pharmacokinetics of antibiotics in CF patients differ compared to most other individuals. The volume of distribution and total body clearance is increased in CF patients for hydrophilic drugs such as aminoglycosides, penicillins, and cephalosporins. Specifically, the initial dose of aminoglycosides is higher in CF patients when compared to the general population and adjusted based on patient-specific pharmacokinetic parameters.

⑥ CF is a multi-system disease requiring a multimodal treatment approach administered through a multidisciplinary team to provide optimal care and the best patient outcomes. With the advancements in science and treatment options, not only is the quality of life for cystic fibrosis patients increasing but their lifespan is extending.

BEYOND THE BOOK

BEYOND THE BOOK

1. Create a concept map that interlinks cystic fibrosis pathophysiology and its complications with appropriate medication regimens. This activity will help develop the learner's application of treatment strategies with the underlying pathophysiology and complications of the disease.
2. Review the case study "Cystic Fibrosis: Blood, Sweat, Lungs, and Gut Level III," by Novak, Kimberly J. in the Pharmacotherapy Casebook: A Patient-Focused Approach, 11e Eds. Terry L. Schwinghammer, et al. McGraw Hill, 2020, https://accesspharmacy.mhmedical.com/content.aspx?bookid=2868&sectionid=242179467. Write a pharmacokinetic SOAP note based on the serum tobramycin concentrations obtained in the case. This activity will help develop the learner's application of pharmacokinetic principles and practice communication of recommendations based on patient-specific pharmacokinetic parameters.

INTRODUCTION

Cystic Fibrosis (CF) is the most common autosomal recessive disease in the Caucasian population with a prevalence of approximately 1/3,500 live births.[1] First described in 1938, CF was initially thought to be a disease of malnutrition since malnutrition was the cause of death in these children in early childhood but is now known to be a genetic disorder.[2] Mutations of a gene that encodes the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride-conducting transmembrane channel, impairs the regulation of chloride and other anion transport and results in thickened, viscous secretions in many organ systems, including the pulmonary, biliary, pancreatic, intestinal, and reproductive systems.[3] The resultant organ dysfunction not only encapsulated the initial findings of malnutrition due to maldigestion and malabsorption but also signifies the progressive lung disease that now highlights the major cause of morbidity and mortality in most patients.

CF currently affects more than 30,000 people in the United States and approximately 80,000 people worldwide. However, CF is no longer exclusively a childhood disease. Advancements in therapy have enabled most CF patients to live into adulthood.[2] More than half of the CF patients in the United States are adults.[4] The median predicted survival age has steadily increased over the past decade and was approximately 48 years in 2019. It is likely the median survival age will continue to increase as the impact of newer therapies such as the CFTR modulators are realized.

EPIDEMIOLOGY

Cystic Fibrosis occurs in a classic single-gene (Mendelian) autosomal recessive pattern.[5,6] Autosomal recessive patterns of inheritance require both parents to be carriers of the gene. CF occurs most commonly in the populations of people of northern European ancestry where the predominant mutation is delta F 508 (which is a deletion of phenylalanine at position 508 on the long arm of chromosome 7 also known as F508del).[5,6] This mutation accounts for approximately 70% of all mutations. The disease incidence in other populations is less defined but has been reported to be 1 in 17,033 live births for Black American patients, 1 in 12,000 in mixed-race South Africans, and 1 in 90,000 in Asian populations (Chinese, Japanese, and Filipino) living in Hawaii.[7] To date more than 2000 gene variants have been identified many of which have been associated with disease causation.[8]

ETIOLOGY

The gene for CF, localized to the long arm of chromosome 7, encodes a protein of 1480 amino acids residues.[9] This CFTR protein is found in the apical membrane of epithelial cells and regulates the transepithelial transport of chloride, other ions, and water.

The CFTR mutations can be grouped into six classes (Fig. 47-1).[6,10] Classes 1 to 3 are known as minimal function mutations as they confer no, or hardly any, CFTR function. Class 1 mutations, referred to as protein production mutations, affect the transcription of CFTR by the formation of premature stop codons into the messenger RNA. This results in a total absence of the CFTR protein. Class 2 mutations, protein processing mutations, or trafficking defects, involve intracellular processing of the CFTR protein. CFTR protein is produced but is misfolded, making it unstable and leading to degradation. The most notable Class 2 mutation is delta F 508. Class 3 mutations (defective channel regulation or gating mutations) alter the regulation of CFTR. While the CFTR is intact and incorporated into the cell membrane surface, this mutation affects channel activation, reducing its opening probability. Class 4 mutations, referred to as conduction mutations, affect the chloride conductance of CFTR. The CFTR protein channel can be activated to open and secrete chloride but the conductance is reduced. Class 5 mutations result in the production of CFTR protein with normal chloride secretion but a decreased number of CFTR channels. Finally, Class 6 mutations result in an accelerated CFTR turnover from the cell surface resulting in decreased CFTR stability.

FIGURE 47-1

Mutations in the cystic fibrosis transmembrane conducatance regulator (CFTR) gene can be divided into six classes. Class I mutations result in no protein production. Class II mutations (including the most prevalent, Phe508del) cause retention of a misfolded protein at the endoplasmic reticulum, and subsequent degradation in the proteasome. Class III mutations affect channel regulation, impairing channel opening (eg, Gly551Asp). Class IV mutants show reduced conduction - ie, decrased flow of ions (eg, Arg117His). Class V mutations cause substantial reduction in mRNA or protein, or both, Class VI mutations cause substantial plasma membrane instability and and include Phe508del when rescued by most correctors (fPhe508del). Patients with at least one mutation of class 4, 5, or 6 typically have a later onset of disease, lower sweat chloride values, slower decline in lung function, less chronic *Pseudomonas aeruginosa* infections, less CF-related diabetes, and lower treatment burden.[11] Together, these mutations are called residual function mutations.

PATHOPHYSIOLOGY

CF is caused by a mutation in the CF transmembrane conductance regulator gene.[12] The CFTR protein produced by this gene regulates the movement of chloride and sodium ions across epithelial cell membranes (Fig. 47-2). CFTR functions primarily as an apical anion channel of chloride and bicarbonate, rather than an active pump. Loss of apical CFTR leads to reduced chloride and bicarbonate secretion, resulting in a buildup of thick mucus throughout the body including in the lungs, pancreas, liver, intestine, and reproductive tract. This defect also leads to increased salt content in sweat gland secretions. Thus, cystic fibrosis is a multisystem disease with most patients experiencing a wide range of symptoms and diverse organ complications.

FIGURE 47-2

Illustration of the normal and abnormal movement of chloride and sodium ions across epithelial cell membranes. ENaC, amiloride sensitive epithelial Na+ channel; CFTR, cystic fibrosis transmembrane conductance regulator; CaCC, calcium-activated Cl− channels.

Pulmonary Manifestations

Although CFTR mainly functions as an anion transporter, it also regulates numerous processes, including fundamental aspects of airway defense and inflammatory cell function.[13] The release of water and electrolytes onto the airway surface is driven in large measure by CFTR-dependent fluid secretion through both the sweat glands and the surface epithelia. A CFTR deficiency leads to diminished airway surface hydration, thickened mucus secretions, and accumulation that compromises the airway lumen, submucosal gland hyperplasia, and impaired mucociliary transport.[14,15] Airway disease likely begins in the small airways with the development of bronchiectasis whereby the walls of the bronchioles are thickened from infection and inflammation. This leads to irreversible changes that encourage continued infection, accelerate disease pathogenesis, and ultimately, obstructive pulmonary disease.[15]

The inflammatory response contributes to a pro-inflammatory state that sets up chronic infections and further tissue damage.[16] The massive influx of neutrophils to the airways further exacerbates inflammatory cell recruitment, perpetuating a cycle of inflammation and damage. In addition, in the CF airways, neutrophils undergo necrosis instead of apoptosis and clearance by alveolar macrophages that occurs in healthy lung tissue. This necrosis leads to the release of intracellular contents further eliciting a persistent inflammatory response. This exaggerated inflammatory process plays an essential role in the progression of airway wall remodeling, lung damage, and lung function decline in CF patients. With the colonization by bacterial pathogens, overly exaggerated protective mechanisms result in the release of proteases, reactive oxygen/nitrogen species, and proinflammatory chemokines. CFTR also regulates anion secretions through other chloride channels such as transmembrane member 16a (TMEM16a; also known as anoctamin-1) and contributes to airway pH regulation through chloride exchangers, such as anion exchanger type 2. Dysfunction of these mechanisms results in diminished or absent bicarbonate secretion leading to an acidic pH airway surface liquid in cystic fibrosis. This may lead to changes in the highly pH-sensitive innate defensins and defective bacterial killing.[17,18] CFTR also has a direct effect on neutrophil killing, as it affects degranulation by interfering with granule trafficking as peripheral neutrophils release fewer secondary and tertiary granule components compared with control cells. Activation of the low-molecular-mass GTP-binding protein Rab27a, involved in the regulation of granule trafficking, is also defective.

Chronic pulmonary infections adversely impact the quality of life and can lead to respiratory failure which is the leading cause of death in patients with CF.[19] The decreased airway surface liquid volume leads to a collapse of respiratory cilia, impaired mucociliary clearance, and mucus retention on the lower airways. Under these conditions, inhaled microorganisms cannot be efficiently cleared and this predisposes CF patients to chronic bacterial infection and recurrent pulmonary exacerbations. The most common microorganisms that cause chronic pulmonary infections are *P. aeruginosa*, *Staphylococcus aureus*, S*tenotrophomonas maltophilia*, and *Burkholderia cepacia*. CF patients are not infected at birth but acquire these organisms over time. Viral infections such as Rhinovirus and Influenza A and B and fungal infections such as Aspergillus fumigatus are also prevalent in the population.

Finally, mucus accumulation in the lower airways is the main feature of CF lung disease. The major component of mucus in CF is not mucin from mucus-producing cells but rather a pus that includes viscous materials such as polymerized DNA from degraded neutrophils.

Upper Airway Manifestations

Due to the increased viscous mucus that accumulates in the sinuses, chronic rhinosinusitis is common and nasal polyposis is a complication noted in up to 45% of patients.[15] Imbalance of electrolyte transport from CFTR dysfunction reduces airway surface liquid depth and increases the viscosity of mucins in the airway 30 to 60 times higher than seen in patients without CF.[20] Tenacious secretions and tissue inflammation block sinus ostia, which results in hypoxia, mucosal edema, and additional impairment of mucociliary function.

Gastrointestinal Manifestations

Defective CFTR in the pancreatic epithelium results in proteinaceous secretions that block the exocrine ducts and ultimately cause acinar destruction.[14] Pancreatic insufficiency results when >95% of the total pancreatic exocrine function is lost. This then leads to nutrient loss due to the inability to break down nutrients as well as reduced fat-soluble vitamin absorption (Vitamins A, D, E, and K). The early recognition of nutritional deficits is vital. Poor growth and malnutrition adversely affect pulmonary function and can lead to premature death.

CFTR is also present in the GI epithelium and, like the lung, reduced chloride and fluid secretion lead to mucus buildup in the intestines resulting in obstruction of the intestines. Impaired bowel transit can lead to frequent gastro-esophageal reflux, distal intestinal obstruction syndrome, and constipation, depending on the site of obstruction.

Hepatic involvement is also common. Up to one in three patients have evidence of hepatic steatosis, cholelithiasis, ductal stenosis, or focal biliary cirrhosis due to the accumulation of viscous secretions that clog the biliary tract.[21] Biliary cirrhosis typically becomes evident in late childhood or early adolescence and leads to portal hypertension. Patients with liver disease may be classified into the following categories: (1) liver involvement with cirrhosis/portal hypertension or (2) liver involvement without cirrhosis or portal hypertension. Advanced liver disease may be found in patients with PI. Risk factors for advanced liver disease include male gender and the presence of alpha-1 antitrypsin Z allele. Typically, patients with a CFTR mutation that belongs to class I to III are more likely to have abnormalities of the hepatobiliary system.

Endocrine Manifestations

Cystic fibrosis-related diabetes (CFRD) is increasingly common as more patients with CF live longer. CFRD is clinically distinct from type 1 and type 2 diabetes mellitus. CFRD is thought to be related to loss of insulin-producing islet cells due to autolysis and fatty infiltration of the pancreas, pancreatic duct obstruction from the accumulation of viscous secretions, and decreased islet cell mass, all of which lead to both insulin and glucagon deficiency, altered intestinal motility, and delayed gastric emptying.[22] Unlike type 1 diabetes, the loss of islet cells in CFRD is not due to an autoimmune process.[23] The course is progressive in nature, and patients may move back and forth between an impaired state and CFRD. Uncontrolled CFRD may correlate with pulmonary function decline, weight loss, and *P. aeruginosa.*

Other endocrinological complications of cystic fibrosis include delayed menarche in malnourished adolescent females and reduced bone mineral density, increasing the risk of bone fractures. A bilateral absence of the vas deferens occurs in 98% of males with cystic fibrosis and results in azoospermia. Most males with CF are infertile.

Renal Manifestations

Nephrocalcinosis due to salt and water depletion can result in acute kidney injury and proteinuria.[14] Chronic kidney disease is more common in adult patients and risk factors for its development include diabetes, prior episodes of acute kidney injury, and immunosuppressive regimens associated with prior organ transplantation.

CLINICAL PRESENTATION

CLINICAL PRESENTATION[24–28]

General

- Typical respiratory manifestations include persistent productive cough, hyperinflation of the lung fields, and obstructive findings on pulmonary function tests. Other manifestations may include GI, endocrine, and renal abnormalities.

Diagnosis

- Two diagnostic components and a combination of criteria.[24]
- At least one clinical feature of the disease (such as failure to thrive, malabsorption, chronic sinopulmonary disease), a history of a sibling with the disease, or a positive neonatal screening test.
- The second diagnostic component is the demonstration of CFTR dysfunction which can be established either by sweat testing or molecular genetic testing (Fig. 47-3).[25]
    - The demonstration of CFTR dysfunction using a "sweat test" requires high chloride values in sweat (≥ 60 mmol/L) in two independent measurements on the same day.[24] Values below 29 mmol/L make cystic fibrosis unlikely; values between 30 and 59 mmol/L require further diagnostic testing.
    - Infants identified at risk for CF through newborn screening who have an in-determinate sweat chloride (30–59 mmol/L) and less than 2 known disease-causing CFTR mutations are classified as having Cystic Fibrosis–Related Metabolic Syndrome (CRMS).[27]
    - CFTR-Related Disorder is used for patients who do not meet diagnostic criteria for CF but have clinical disease limited to an isolated CF-related condition or organ system, such as the congenital bilateral absence of the vas deferens (CBAVD).[28]

Signs and Symptoms

- Disease progression results in acute exacerbations with cough, tachypnea, dyspnea, increased sputum production, malaise, anorexia, and weight loss.
- Digital clubbing is often seen in advanced disease as well. Sinus involvement can present with chronic nasal congestion, headaches, cough, and sleep disturbance.
- Common signs and symptoms of pancreatic insufficiency include steatorrhea, poor weight gain, and failure to thrive.
- In CFRD, patients often do not present with the classic symptoms of diabetes such as polyuria and polydipsia.[23] There may be no symptoms, or there may be poor growth velocity, delayed progression of puberty, and unexplained chronic decline in pulmonary function.

Historically, cystic fibrosis was diagnosed based on presenting symptoms such as meconium ileus, respiratory symptoms (persistent productive cough, wheezing, or any breathing difficulty), or failure to thrive. However, with the newborn screening programs now in place, the number of cases identified prior to presenting with symptoms has greatly increased.

The demonstration of CFTR dysfunction using a "sweat test" requires high chloride values in sweat (≥ 60 mmol/L) in two independent measurements on the same day.[24] Molecular genetic tests constitute the second stage of confirmatory diagnostic testing (See Fig. 47-3). This test also determines which mutations are present.

All 50 states in the United States now require cystic fibrosis tests as part of newborn screening.[26] It is a screening test and not diagnostic. The first-tier screen in all state screening programs involves measuring immunoreactive trypsinogen (IRT), a marker of pancreatic injury. A second-tier test is needed to improve test specificity because the initial IRT can be increased due to perinatal stress, critical illness, CFTR mutation carrier status, and other causes. The second-tier test differs between state newborn screening programs and can include CFTR mutation analysis, measurement of pancreas-associated protein, or repeat IRT. The diagnosis must be confirmed by a positive sweat test or, alternatively, by genetic tests demonstrating 2 disease-causing mutations.

With the increase in newborn screening, new categories of infants who do not meet the classic definition of CF have arisen. Infants identified at risk for CF through newborn screening who have an in-determinate sweat chloride (30–59 mmol/L) and less than 2 known disease-causing CFTR mutations are classified as having Cystic Fibrosis–Related Metabolic Syndrome (CRMS).[27] An additional diagnostic category, CFTR-Related Disorder, is used for patients who do not meet diagnostic criteria for CF, but have clinical disease limited to an isolated CF-related condition or organ system, such as congenital bilateral absence of the vas deferens (CBAVD).[28] Many of these patients have mutations in the CFTR gene that are not considered the classic disease-causing mutations. For example, some patients with CFTR-Related Disorder have the 5T variant which is a common mild variant and causes abnormal splicing of the CFTR gene transcript. Most individuals with two copies of this variant are asymptomatic but some may have an absence of the vas deferens or bronchiectasis. Patients without a definitive diagnosis of CF are continued to be followed for symptom progression and potentially reclassification later in life.

Diagnosis of liver disease can include a physical exam which may reveal ascites, palmar erythema, digital clubbing, scleral icterus, spider hemangiomas, and hepatosplenomegaly.[21] Additionally, evaluation of liver function panel and obtaining lab work for alpha-1 antitrypsin deficiency, Wilson disease, and hemochromatosis should be included. Imaging and a liver biopsy may also be performed to determine the extent of the liver disease and exclude other causes. There are annual labs that can identify CFLD early, these include complete blood count (CBC), prothrombin time, liver function panel, gamma-glutamyl-transferase (GGTP), albumin, cholesterol, and glucose.

In CFRD, patients often do not present with the classic symptoms of diabetes such as polyuria and polydipsia.[23] There may be no symptoms, or there may be poor growth velocity, delayed progression of puberty, and unexplained chronic decline in pulmonary function. Screening for CFRD should occur annually in patients aged 10 and older as recommended by the American Diabetes Association (ADA). Additionally, women with CF who are not previously known to have CFRD and who are contemplating pregnancy should be evaluated for CFRD utilizing a 2-hour, 75-g oral glucose tolerance test (OGTT). If screening has not occurred within the last six months, screening should occur in women prior to conception because women with CF are at higher risk for developing hyperglycemia. Screening is typically done as an OGTT for all patients with CF. An A1c reading of ≥6.5% (48 mmol/mol) may indicate CFRD; however, an A1c should be used in combination with an OGTT as a confirmation of CFRD. Fructosamine, urine glucose, and random glucose levels have low sensitivity in patients with CF. The OGTT should be administered following stable baseline health for at least six weeks and patients should consume at least 150 carbohydrates for three days prior and fast for eight hours prior to the OGTT.

Collect

- Patient characteristics
    - Age
    - Race/ethnicity
    - Sex assignment
    - Gender preferred pronouns
- Symptoms
    - Sputum production color and production
    - Cough
    - Shortness of breath
    - Stool frequency and description
- Diagnostic Screening
    - Newborn screening
    - Genetic mutations

  - Sweat test
- Patient history (past medical history, family history, birth history)
  - History of hospitalizations
  - History of infections (particularly resistant organisms)
  - Complications of CF (eg, CF renal disease, CF lung disease)
  - Past surgical history (eg, G-tube placement)
  - Reproductive history
- Social history
  - Home and work environment (infection control, dedicated space, and time for treatments)
  - Insurance status and income history may be used to qualify for grants
  - Eating habits
- Current medication and history of past medication use, herbals, dietary supplements, and over the counter products
- Objective data
  - Respiratory function (FEV1, oxygen saturation)
  - Nutritional status (height, weight, BMI)
  - Mental status (PHQ-9 and GAD-7)
  - Labwork: CBC, CMP, Lipids, Liver function, Vitamin D
- Immunization status and history

Assess

- Medication effectiveness and safety (reduction in symptoms, ADEs)
- Medication adherence to prescribed medications (schedule, costs, dietary supplements)
- Barriers to medication use
- Adherence to respiratory therapy (vest and technique)
- Nutritional status (BMI, calorie intake)
- Lung function (exacerbations)
- Emotional well-being of patient, family, and caregivers
- Exercise tolerance
- Co-morbidities

Plan*

- Infection control and environmental modifications

- Medication plan (timing, order of medications, doses, route, formulation, frequency, duration)
- Labs
    - CBC and CMP yearly
    - Sputum culture quarterly
    - Liver panel quarterly for the first year of modulator therapy
    - 25-hydroxyvitamin D, retinol, alpha-tocopherol, prothrombin time, PIVKA II, and OGTT annually
- Referrals (endocrinology, urology, gastroenterology, ob-gyn, transplant, infectious disease, audiology, ophthalmology)

Implement*

- Patient/family education on the purpose of each medication
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow up

Follow-up: Monitor and Evaluate

- Results of lab work and sputum cultures
- Medication access and adherence
- Medication changes based on results of lab work
- Sick visits to decrease the need for hospitalization
- Home infusions of antibiotics when necessary and available

*In collaboration with the patient, caregiver, and other healthcare professionals on the team (social worker, dietitian, respiratory therapist, pulmonologist, nurses).

TREATMENT

Desired Outcome(s)

The overall goal of treatment is to enable each person with cystic fibrosis to live a full and productive life. Optimizing treatment to reduce pulmonary exacerbations, delaying colonization by pathogens, and maintaining lung health is key to improving survival. In addition, maximizing adequate nutrition with appropriate dosing of pancreatic enzymes and vitamin supplementation contributes to accomplishing the desired outcomes. Furthermore, with the development of the CFTR modulators and as other disease-modifying therapies become available, every patient should receive treatments that address the underlying pathophysiology of the disease.

General Approach to Treatment

Pulmonary and Sinus

The goal of treatment is to prevent and treat sinusitis and acute pulmonary exacerbations. Routine care goals are to maintain the FEV1 and promote optimal pulmonary function tests. Effective airway clearance is promoted with counseling on the use of appropriate medications and airway clearance techniques (ACT) at least twice a day. Prevention and treatment of bacterial colonization with oral and inhaled therapies are also keys to maintaining lung function.

Gastrointestinal

Optimizing growth and nutrition is done primarily with the use of pancreatic enzyme supplementation. This in turn will promote healthy bowel habits and maintenance of appropriate fat-soluble vitamin levels (Vitamins A, D, E, and K). Vitamin levels are checked at least yearly and some such as Vitamin D can have seasonal variations. Evaluating and supporting needed caloric intake is important to promote good lung function and symptoms of malabsorption are evaluated at every clinic visit. Patients' weight for length or body mass index (BMI) should be maintained at or above the 50th percentile because it has been associated with the best lung functions.

Psychosocial

Each patient will need ongoing education and support to encourage adherence to pharmacological and nonpharmacological therapies. Counseling to help cope with a lifelong disease, as well as guidance to live a fulfilling life, are paramount to successful treatment. Once patients' mutations are determined by genetic testing, it is essential to provide appropriate genetic counseling at the time of diagnosis and periodically thereafter. As patients and significant others reach reproductive age it is key to offer both possible birth control methods and support couples in family planning with education and resources.

Nonpharmacologic Therapy

Exercise, infection prevention control, nutrition, and airway clearance are ways in which a patient with CF can improve mucous obstruction and avoid chronic infections. There is not a specified length of time in which exercise is recommended by the Cystic Fibrosis Foundation, however, the purpose is to loosen mucous and clear the airways.[29] Shorter exercises that are enjoyable and tolerated by patients are the best exercises. Sodium loss may occur during intense exercise, and repletion is necessary to avoid dehydration.

The Cystic Fibrosis Foundation sets forth several recommendations for infection prevention. Patients with CF should engage in regular hand hygiene throughout the day using an antimicrobial soap or alcohol-based hand rub. All patients with CF should adhere to the six-foot rule to reduce droplet transmission. Patients with CF should wear a surgical mask when in a health care setting to reduce transmission or acquisition of CF pathogens.[30]

Patients with CF often need 1.5 to 2 times the number of calories as patients without CF. Nutrition plays an essential role in pulmonary function and bone health. Weight for length is a measure that is used to track patients who are under the age of two and body mass index (BMI) is typically used after the age of two. The CF Foundation recommends that children younger than 2 should reach a weight-for-length ≥ 50th percentile by 2 years of age and children and adolescents 2- to 20 years old should be at or above the 50th percentile for BMI.[31] In adults, women should be encouraged to maintain a BMI of at least 22 and for men, a BMI of 23 is recommended.

Airway clearance techniques (ACT) include percussion and postural drainage, positive expiratory pressure (PEP), active-cycle-of-breathing technique, autogenic drainage, oscillatory PEP, high-frequency chest compression, and exercise. One way to facilitate airway clearance is through the use of a vest. A vest uses high-frequency chest wall oscillation that is performed by a machine. Use of the vest loosens and thins mucus. These sessions typically last about 20 to 30 minutes. Airway clearance may also be done manually by a parent or caregiver. The caregiver uses a variety of hand-to-chest techniques, typically lasting three to five minutes, to help loosen and drain the mucus. These techniques can include clapping with a cupped hand and creating vibration with a flattened hand. The best times to complete chest physical therapy (CPT) is before meals or one and a half hours to two hours after eating. CPT may be performed more frequently if the patient is congested or getting sick.

Pharmacologic Therapy

Genetic Therapies

CFTR Modulators

Understanding the defect with each class of mutations helps identify the role the three classes of CFTR modulators play in the treatment of CF.[32] Even though no cure to treat the underlying cause of cystic fibrosis currently exists, the CFTR modulator class of medications is used to alleviate and correct part of the underlying pathophysiology.

The three classes of CFTR modulators include correctors, potentiators, and amplifiers. Correctors work by increasing the amount of functional CFTR at the cell surface. Medications labeled as correctors include lumacaftor, tezacaftor, and elexacaftor. There are a few additional correctors that are in the pipeline which include posenacaftor, dirocaftor, and ABBV-2222, which are currently in clinical trials. There is only one potentiator on the market, ivacaftor. The role of the potentiator is to keep the channel open to increase the transport of chloride in and out of the cell. VX-561 is deuterated ivacaftor meaning that it is more stable in the body than the current formulation of ivacaftor and would be able to be taken once daily. This agent is currently in phase 2 trial. The last class of CFTR modulators is the amplifiers which include one agent in the pipeline, nesolicafator. This class of medications works by increasing the amount of CFTR protein in the cell, which provides more CFTR for correctors and potentiators to act upon.

The CFTR modulators have mutation-specific and age-specific indications. General recommendations for the selection of a CF modulator are therefore based on the age of the patient and the mutation. For delta F 508 homozygotes older than 6 years of age, elexacaftor/tezacaftor/ivacaftor combination is recommended. For delta F 508 homozygous children between 2 and 5 years of age should be started on lumacaftor/ivacaftor combination. Patients can be transitioned from dual therapy to triple therapy as they increase in age. For delta F 508 heterozygous patients who are 6 years of age or older, triple therapy is recommended. Tezacaftor/ivacaftor may be used for children 6 and older whereas ivacaftor alone may be used in infants greater than 4 months old. As the FDA approves additional modulators and adjusts the age-specific labeling of current modulators, recommendations for a CF modulator will need to follow suit.

Even though adverse effects with the CFTR modulators are often mild, monitoring for the elevation of transaminases and cataracts is currently recommended. Assessments of transaminases (ALT, AST, and/or bilirubin) are recommended for all patients prior to initiating the currently approved CF modulators, every 3 months during the first year of treatment, and annually thereafter. In addition, baseline and follow-up ophthalmological examinations are recommended in pediatric patients initiating treatment with these agents. Of particular note, a subgroup of patients develops chest discomfort and dyspnea after initiating the combination of lumacaftor/ivacaftor.[33] These patients tend to have worse baseline lung function. Initiating treatment with a one-half dose for the first one to two weeks may help prevent treatment discontinuations in patients with severe lung disease.[34] However, there was no increase in chest discomfort, bronchospasm, dyspnea, or wheezing with tezacaftor as seen with lumacaftor/ivacaftor.[35,36]

Caution should also be used when CFTR modulator medications are used concomitantly with CYP3A4 inducers or inhibitors. Even though tezacaftor/ivacaftor are substrates of CYP3A and co-administration with strong CYP3A inducers is not recommended, texacaftor/ivacaftor combination appears to have fewer drug interactions than the lumacaftor/ivacaftor combination.

Current CFTR modulators are administered with a high-fat meal to improve absorption. Some examples of high-fat foods include eggs, peanut butter, avocado, butter, cheese pizza, and whole-milk dairy products.

CFTR Correctors

Lumacaftor

Lumacaftor is manufactured in combination with ivacaftor which works to potentiate and enhance chloride transport.[37] This combination product is currently approved for use in patients homozygous for delta F 508 for ages two and up. The formulation usually is dosed as two tablets of lumacaftor 200 mg/ivacaftor 125 mg every 12 hours with fat-containing food to help with medication absorption. See Table 47-1 for dosing and dosing formulations.

TABLE 47-1

Lumacaftor Dosing and Dosing Formulations

Dosage Form	Age	Recommended Dose	Counseling Points
Granules	2-5 years old	• < 14 kg one packet lumacaftor 100 mg/ivacaftor 125 mg every 12 hours • >14 kg one packet lumacaftor 150 mg/ivacaftor 188 mg every 12 hours	• Take with fat-containing food • Shake the packet gently to settle the granules, after opening the packet, pour the granules into 1 teaspoon of soft food or liquid in a small container, food or liquid should be at or below room temperature, and once mixed should be given within 1 hour, the entire dose should be consumed
Tablets	6 years and older	• 6-11 years old • 2 tablets lumacaftor 100 mg/ivacaftor 125 mg every 12 hours • 12 years and older • 2 tablets lumacaftor 200 mg/ivacaftor 125 mg every 12 hours	

The outcomes that were studied when looking at the efficacy of lumacaftor/ivacaftor included FEV1, BMI, and exacerbations.[38] In homozygous delta F 508 participants, clinical studies demonstrated statistically significant improvements in percent predicted FEV1 along with improvements in body mass index and quality-of-life measures at both low and high doses (400 or 600 mg of lumacaftor in combination with ivacaftor 250 mg every 12 hours for 24 weeks). In addition, pulmonary exacerbations were significantly reduced when compared to placebo. In heterozygous patients for the delta F 508mutation, lumacaftor/ivacaftor does not appear to have the same clinical benefits.[39]

Tezacaftor

Tezacaftor is additionally found in combination with ivacaftor.[36] It was previously approved in patients 12 and older but has now expanded to patients ages 6 and older. This combination is different from lumacaftor/ivacaftor due to it being indicated in patients that are homozygous for F508del or those who have at least one mutation that is responsive to tezacaftor/ivacaftor. At least 150 different mutations are eligible for tezacaftor/ivacaftor.

Weight-based dosing is used with recommendations made for those children greater than 30 kg and those children less than 30 kg. See Table 47-2 for dosing of tezacaftor/ivacaftor. The dosing is also twice daily, similar to lumacaftor/ivacaftor, and still needs to be taken with fat-containing food.

TABLE 47-2

Tezacaftor/ivacaftor Dosing

Weight Based, Ages 6-11	Morning	Evening
<66 lbs or less than 30 kg	One Tezacaftor 50 mg/ivacaftor 75 mg tablet	One ivacaftor 75 mg tablet
≥66 lbs or greater than 30 kg	One Tezacaftor 100 mg/150 ivacaftor tablet	One ivacaftor 150 mg tablet
Patients who are greater than 12 years of age		
Ages greater than 12	One Tezacaftor 100/ivacaftor 150 mg tablet	One ivacaftor 150 mg tablet

As with lumacaftor/ivacaftor trials, tezacaftor/ivacaftor also demonstrated improvements in FEV1, disease-related quality of life, and rate of pulmonary exacerbations when compared to placebo.[36] Additionally, it was found that BMI had improved slightly. These effects were seen in both delta F 508 homozygous and heterozygous patients.

Elexacaftor

The newest approved CFTR modulator is the first triple combination that includes elexacaftor/tezacaftor/ivacaftor.[40] Elexacaftor and tezacaftor have slightly different mechanisms although both are still known as correctors. Elexacaftor corrects a flaw during the formation of the delta F 508 CFTR protein that helps get more functioning CFTR proteins to the surface. This is known as a next-generation CFTR when compared to tezacaftor. Additionally, the triple combination only requires a single delta F508 mutation. Elexacaftor/tezacaftor/ivacaftor is currently only approved in those ages 6 and older. See Table 47-3.

TABLE 47-3

Elexacaftor Dosing

Age	Morning	Evening
6-12 years weighing less than 30 kg	Two tablets, each containing elexacaftor 50 mg/tezacaftor 25 mg/ivacaftor 37.5 mg	One tablet of ivacaftor 75 mg
6-12 years weighing more than 30 kg	Two tablets, each containing elexacaftor 100 mg/tezacaftor 50 mg/ivacaftor 75 mg	One tablet of ivacaftor 75 mg
12 years and older	Two tablets, each containing elexacaftor 100 mg/tezacaftor 50 mg/ivacaftor 75 mg	One tablet of ivacaftor 150 mg

Clinical trials, in both homozygous and heterozygous delta F 508 patients, evaluating the efficacy of the triple combination demonstrated an increase in percent predicted FEV1, a decrease in pulmonary exacerbations, and sweat chloride concentrations, and an improvement in respiratory symptoms as measured by a standardized questionnaire.[41,42] When compared to dual therapy, tezacaftor/ivacaftor, improvements were still noted in FEV1, sweat chloride concentrations, and respiratory symptoms.

Similar outcomes were noted in patients with advanced lung disease (< 40% percent predicted FEV1).[41,43,44] These patients experienced an increase in FEV1, a decrease in chronic oxygen therapy and noninvasive ventilation, an increase in mean body weight, and a decrease in enteral feeding requirements.

CFTR Potentiator

Ivacaftor

Ivacaftor was the first medication approved for patients with CF that targeted the CFTR protein.[45] It is a CFTR potentiator that keeps the channels open at the cell surface to increase the transport of chloride in and out of the cell. Ivacaftor needs the CFTR protein to be present at the cell surface in order to be efficacious. The mutation first studied with ivacaftor was the missense mutation, G551D. Approximately 4% to 5% of patients with cystic fibrosis have the G551D mutation on one allele of the CFTR protein. Ivacaftor is indicated in patients who have one mutation in the CFTR gene that is responsive to ivacaftor potentiation based on clinical and/or in vitro assay data. The FDA approved 97 additional mutations for use with ivacaftor based on in vitro demonstration of modulator-induced increase chloride transport and clinical benefit. The in vitro-responsive mutations did show clinical benefits in a small randomized trial. Ivacaftor is approved for patients as young as four months old and is available as granule packets for children 4 months to 5 years and tablets for patients 6 years of age or older. As with the other agents, dose reductions are needed in patients with hepatic impairment. See dosing Table 47-4.

TABLE 47-4

Ivacaftor Dosing

Dosage Form	Age	Recommended dose	Counseling points
Granules	4 months to 6 months	One 25 mg packet every 12 hours	Shake the packet, and pour into 1 teaspoon (5 mL) with soft food or liquid that is at or below room temperature. (Ex: breast milk, formula, applesauce, milk, yogurt, juice)
	6 months to 6 years old	• 11 pounds (5 kg) to less than 15 pounds (6.8 kg): one 25 mg packet every 12 hours • 15 pounds (6.8 kg) to less than 31 pounds (14 kg): one 50 mg packet every 12 hours • 31 pounds (14 kg) or more: one 75 mg packet every 12 hours	
Tablet	6 years and older	One tablet 150 mg twice daily	With fat-containing food

In patients with a G551D mutation, ivacaftor increased the FEV1, decreased sweat chloride, reduced pulmonary exacerbations, improved pulmonary symptoms, and increased body weight.[46] The long-term effects demonstrated lower risks of death, hospitalizations, and transplantations.[47] Lower prevalence of *P. aeruginosa* along with lower acquisition rates and higher clearance rates have also been noted in patients on ivacaftor monotherapy.[48–50]

As with the correctors, elevations in hepatic enzyme concentrations and noncongenital lens opacities have also been reported with ivacaftor. Therefore, ivacaftor monitoring includes cataracts at baseline and then annually, as well as liver function tests at baseline and every 3 months during the first year of treatment and then annually thereafter.

CFTR Amplifiers

Amplifiers work by increasing the amount of CFTR protein in the cell and stabilizing CFTR mRNA through translational elongation.[51] In phase II trials, nesolicaftor appears well-tolerated and did increase the production of CFTR; however, it did not impact lung function in patients taking tezacaftor/ivacaftor with two copies of the F508del mutation.

Airway Clearance Therapy

Airway clearance therapies are recommended for all patients with CF for clearance of sputum, maintenance of lung function, and improved quality of life.[52] Cystic fibrosis is characterized by dehydration of the airway surface liquid and impaired mucociliary clearance. Dehydration occurs as a direct result of the inherited abnormality in the cystic fibrosis transmembrane regulator protein which leads to a reduced chloride section and increased absorption of sodium and water from the airway surface liquid.[53] The dehydrated mucus layer eventually becomes adherent to the airway surface.[54] This tenacious adhesive mucus, leading to airway obstruction, creates an environment conducive to the growth of bacteria followed by a neutrophilic host response in the airway lumen. Subsequently, the DNA from dead neutrophils left in the airways further increases the viscosity of already abnormal secretions. Dehydration of the airway surface liquid layer is the primary initiating event in CF-related lung disease; therefore, therapeutic interventions to improve mucus clearance and reduce the obstruction, infection, and inflammation remains a cornerstone of treatment in CF.[29]

In addition to non-pharmacological measures to facilitate mucus clearance, pharmacologic therapies including mucolytics such as dornase-alfa and hyperosmolar agents such as aerosolized hypertonic saline are also used to improve mucus clearance. In addition, bronchodilators are utilized to support ACT by opening the airway to facilitate the removal of secretions along with deeper deposition of other inhaled medications into the smaller airways. Bronchodilators should be administered prior to CPT or other ACT techniques.

Mucoactive Agents

Dornase alfa (Recombinant human DNase)

Dornase alfa (recombinant human DNase, rhDNase), an enzyme that selectively hydrolyzes the extracellular DNA in the sputum of CF patients and reduces sputum viscoelasticity, is FDA indicated in conjunction with standard therapies for the management of CF patients to improve pulmonary function.[55] The recommended dosage is one 2.5 mg single-use ampule inhaled once daily using a recommended nebulizer; however, some patients may benefit from twice-daily administration. The most common adverse reactions (occurring in ≥3% of patients treated with dornase alfa over placebo) seen in clinical trials in CF patients were: voice alteration, pharyngitis, rash, laryngitis, chest pain, conjunctivitis, rhinitis, decrease in FVC of ≥10%, fever, and dyspnea.

Both short-term and long-term clinical trials have demonstrated improvement in lung function as measured by FEV_1 as well as reductions in exacerbations requiring the use of parenteral antibiotics compared to placebo.[56–60] Increases in FEV1 have been noted in both short-term studies lasting from 1 to 2 weeks in duration and in long-term studies lasting from 24 weeks to 3 years.

The CF guidelines recommend the chronic use of dornase alfa to improve lung function and reduce exacerbations in all cystic fibrosis patients ≥ 6 years of age and older with asymptomatic/mild disease as well as moderate to severe disease.[61]

Hypertonic Saline (Nebusal™ 4 ml 7%)

Hypertonic saline acts as an osmotic agent which draws water into luminal secretions resulting in the restoration of airway hydration.[54] It is a solution possessing an osmotic pressure greater than that of a physiologic isotonic salt solution (0.9%NaCl).[62] By drawing water from CFTR defective airway epithelial cells, the periciliary layer becomes rehydrated and mucociliary clearance reestablished.[63,64]

In CF patients, 7% hypertonic saline has been shown to be safe, well-tolerated, and effective in restoring mucus clearance, reducing disease exacerbations, and slowing progressive airway obstruction. Short-term administration is associated with improved lung function, increased mucociliary clearance for at least 8 hours in a dose-dependent manner, and increased sputum expectoration.[65] Among infants and children with cystic fibrosis less than 6 years old, the use of inhaled hypertonic saline compared with isotonic saline did not reduce the rate of pulmonary exacerbations over 48 weeks of treatment.[66] In the majority of trials hypertonic saline was used after pre-treatment with bronchodilators and as an adjunct to chest physiotherapy; in both cases, this may be important to ensure its efficacy.[67]

As intolerability due to oropharyngeal irritation and bronchospasm generally relates to the concentration of hypertonic saline and its rate of delivery, the selection of a dose for an individual patient is typically made by determining the maximally tolerated concentration.[54] For individuals with CF, 6 years of age and older, the Cystic Fibrosis Foundation recommends twice-daily use of inhaled hypertonic saline to improve lung function and quality of life and reduce exacerbations.[61]

Mannitol

Inhaled mannitol, an osmotic agent with a high molecular weight, has been proposed as an additional strategy to improve the airway surface hydration by the slow influx of water through a pericellular pathway and mucociliary clearance in patients with CF.[62]

A two-week course of inhaled mannitol in patients with CF resulted in an increase in mean FEV1 from baseline as well as mean FEF_{25-75} compared with placebo.[68] While an international trial assessing the effect of inhaled dry powder mannitol on lung function in CF showed a sustained clinical benefit, there have been no large randomized trials comparing the effect of hypertonic saline versus mannitol.[69]

Inhaled mannitol is considered a second line as a replacement for hypertonic saline in adult patients who fail the combination of hypertonic saline and dornase alpha. Inhaled mannitol was only recently approved by the FDA for use in cystic fibrosis adult patients.

Antibiotics

Infection is one of the main influences on the morbidity and mortality of CF and CF lung disease. Treating infections in CF involves not only antibiotics but chest physiotherapy and inhaled mucolytics play an important adjunction role. Most patients with CF develop chronic bacterial infections; however, the goal of antibiotic treatment is to delay the colonization by pathogens as long as possible. The prevalence of bacterial type varies with age; the most common pathogens include *P. aeruginosa, Staphylococcus aureus,* methicillin-resistant *Staphylococcus* (MRSA)*, Burkholderia cepacia complex, and nontuberculous mycobacteria.*

CF patients have an increased susceptibility to *P. aeruginosa* which is an independent risk factor for a decline in pulmonary function and decreased survival.[70,71] With chronic infection, *P. aeruginosa* converts from “dry” to a “mucoid” phenotype with the production of an alginate biofilm and becomes much more difficult to treat leading to a worse prognosis. *S. aureus* is another pathogen commonly found in the respiratory secretions of CF patients. Co-infection with *S. aureus* and *P. aeruginosa* has an independent and additive effect on airway inflammation.[72] As with *P. aeruginosa*, chronic infection with *B. cepacia* complex is associated with an accelerated decline in pulmonary function and shortened survival.

Strategies should be employed to prevent *P. aeruginosa* acquisition including measures to prevent transmission between CF patients and early eradication of both *P. aeruginosa* and *S. aureus* with appropriate treatment regimens. The CF Foundation recommends a 28-day cycle of inhaled tobramycin for the treatment of patients with newly acquired *P. aeruginosa*. Other regimens have been evaluated but were not as effective as inhaled tobramycin or had similar outcomes as inhaled tobramycin. Eradication protocols for MRSA are more difficult but can be offered to highly selected patients who are capable of following the protocol. The regimen typically includes oral rifampin, oral trimethoprim-sulfamethoxazole, nasal mupirocin, chlorhexidine oral rinses, body wipes, and environmental decontamination.[73]

Inhaled Antibiotics

Chronic colonization with *P. aeruginosa* necessitates chronic treatment with inhaled antibiotics. Currently available regimens include tobramycin, aztreonam lysine, and colistin with all of these agents administered initially in a cyclic phase (28 days on followed by 28 days off) or alternatively as continuous treatment by alternating in 28-day cycles between two different inhaled antibiotics.

Inhaled tobramycin is recommended as a first-line treatment. Inhaled aztreonam may be used in patients who do not tolerate tobramycin, whose pulmonary status is declining while on inhaled tobramycin, or who is or attempting to become pregnant. Adherence may be better with inhaled tobramycin because it is administered twice daily versus three times a day with aztreonam. Conversely, the aztreonam dose is delivered in less than three minutes whereas tobramycin requires a 15 to 20-minute nebulization. If patients do not tolerate either tobramycin or aztreonam or pulmonary function continues to decline on either agent or both agents, inhaled colistin is an alternative. Inhaled colistin does not have the renal toxicity or neurotoxicity typically seen when administered intravenously and is administered twice daily for 28 days, alternating with 28 days off treatment.

Oral Azithromycin

Azithromycin has demonstrated clinical benefits in CF patients with chronic infection with *P. aeruginosa*. These benefits do not appear to be exclusively related to its antimicrobial effects but also an anti-inflammatory effect.[74–77] The antimicrobial effects center around the ability of macrolides to reduce the ability of *Pseudomonas* to produce biofilms whereas the anti-inflammatory effect relates to azithromycin’s ability to suppress the excessive inflammatory response noted in CF patients. In CF patients 6 years of age and older who are chronically infected with *P. aeruginosa,* azithromycin is typically prescribed as a 10 mg/kg dose administered three times a week. Smaller daily dosing rather than three times a week dosing could also be used with similar efficacy. Azithromycin may also be initiated at the time of a first positive culture for *P. aeruginosa* in children as young as 6 months and continued for 18 months rather than waiting until becoming chronically infected in order to initiate therapy.[78] Azithryomycin therapy can be discontinued after multiple negative cultures over the previous year. Macrolide therapy should not be initiated in patients with a positive sputum sample for nontuberculous mycobacteria. The use of oral azithromycin may reduce the efficacy of inhaled and intravenous tobramycin. In retrospective studies, the concurrent use of tobramycin (either acute or chronic therapy) and azithromycin were associated with less improvement in lung function based on FEV1 when compared to tobramycin use alone.[79–82]

Anti-inflammatory Agents

Oral ibuprofen has also been used in cystic fibrosis for its anti-inflammatory properties and limited data has demonstrated a slower decline in lung function when used at a high dose in children who have good lung function (FEV1 > 60% [0.6] predicted).[61,83,84] However, the need for pharmacokinetic monitoring and the risk of side effects have restricted its use. A serum concentration between 50 and 100 mcg/mL (mg/L: 242- 485 µmol/L) is needed.[85]

Inhaled glucocorticoids are only recommended in cystic fibrosis patients with a co-diagnosis of asthma.[61,86] These agents should not be routinely used in patients with cystic fibrosis without definite signs of asthma. Other agents that are not recommended in cystic fibrosis include chronic use of systemic glucocorticoids and cromolyn due to a lack of efficacy, potential for adverse effects, and increased expense.

Pancreatic Disease

Pancreatic exocrine insufficiency (PI) occurs in cystic fibrosis patients as a result of pancreatic duct obstruction due to a viscous exocrine fluid that congeals in the proximal pancreatic ducts.[87] Pancreatic function correlates strongly with genotype with 60% of infants being affected at birth. Patients with two “severe” CFTR mutations usually are associated with PI.[88–90] If left untreated, PI can lead to growth failure, weight loss, abdominal bloating, foul-smelling stools, or diarrhea.

The most common way to screen and diagnose pancreatic insufficiency in patients with cystic fibrosis is the use of the fecal pancreatic elastase-1 test. When values of the fecal pancreatic elastic-1 test result in a value of less than 100 micrograms/gram, it is likely, given the specificity and sensitivity of the elastase test, that the patient is pancreatic insufficient. Patients are often tested for PI at diagnosis and annually if deemed to be pancreatic sufficient.

Pancreatic Enzymes

Pancreatic enzyme replacement therapy (PERT) is the treatment of choice. PERTs are a combination of lipase, protease, and amylase. The PERT dose is generally expressed in lipase units. Typically, PERTs are known to increase fat absorption and provide more consistency in stool frequency and consistency when compared to placebo. There are multiple formulations of PERTs, however, the formulations are not interchangeable as recommended by the Cystic Fibrosis Foundation Guidelines.[91] High doses of PERT could lead to colonic stricture therefore doses of PERT should not exceed 25,000 lipase units per kilogram per meal. Recommended doses are provided with three meals a day and with two to three snacks a day. The snack doses are traditionally half the dose at meal times. It is important to ensure the doses are taken prior to eating and not during or after eating. Enzymes can always be opened, and the contents may be mixed with small amounts of applesauce or alkaline food but should not be crushed or allowed to sit in food. Doses may be titrated based on symptoms of malabsorption such as foul-smelling stools, weight loss, abdominal bloating, or diarrhea. Prior to increasing the dose always take into consideration adherence, dietary factors, liver disease, intestinal hyperacidity, and abnormal intestinal motility. Dosing is also provided similarly when patients are on continuous overnight gastrostomy tube feedings.

There are six different FDA-approved pancreatic enzymes each consisting of various amounts of the combination of lipase, protease, and amylase. Most products are proprietary and there is only one generic pancreatic enzyme formulation available. Each formulation of pancreatic enzymes has different characteristics. Some are delayed-release capsules. One product contains bicarbonate-buffered enteric-coated microspheres, this raises the pH of the duodenal environment to help delay the enzymes’ inactivation by the stomach acid. Another product has a non-enteric coat and thus must be taken with a proton pump inhibitor to reduce the enzymes from being broken down in the stomach too quickly.

Common adverse events from pancreatic enzymes include headache, abdominal pain, flatulence, and cough. Some of these events may be related to malabsorption and may require dose increases. A dose-limiting side effect is fibrosing colonopathy as previously described.

Vitamins

Patients with CF, especially those that are pancreatic insufficient are at increased risk for fat-soluble vitamin deficiency. The fat-soluble vitamins include A, D, E, and K. Supplementation of these vitamins should begin as soon as CF is diagnosed and at typically higher doses than recommended for the general population. Monitoring of serum retinol, 25-hydroxyvitamin D, alpha-tocopherol, prothrombin time, and PIVKA II for assessment of vitamin K deficiency should occur at least annually.

Vitamin D deficiency is probably the most commonly studied vitamin deficiency in CF patients and appears to have an impact on inflammation and maintenance of bone health. The cystic fibrosis foundation has guidelines specifically for vitamin D to ensure that the serum 25-hydroxyvitamin D levels remain at least at 30 ng/mL (75 nmol/L) or higher in all patients with cystic fibrosis.[92] Vitamin D3 or cholecalciferol is the currently recommended oral supplement by the CF Foundation as opposed to vitamin D2, ergocalciferol.

Specific CF-formulated vitamins come in all formulations from drops, chewables, soft gels, and tablets. In addition, individual supplements may also be needed for continued vitamin-specific deficiency.

Pulmonary Exacerbations

Pulmonary infection is a major contributor to CF lung disease. A typical clinical course in most CF patients includes acute episodes of worsening pulmonary status with a decrease in FEV1 along with worsening symptoms such as increased cough and sputum production. Although viruses such as coxsackie/echovirus, rhinovirus, respiratory syncytial virus, parainfluenza, adenovirus, and influenza are often detected during acute exacerbations in children, most patients with CF also have a bacterial infection of the airways that are the same pathogens associated with chronic infections. These bacterial pathogens include *P. aeruginosa, S. aureus, B. cepacia* complex, non-typeable *Haemophilus influenzae, Stenotrophomonas maltophilia, Achromobacter* species, and nontuberculous mycobacteria. Treatment of pulmonary exacerbations requires a multimodal approach including antibiotics, chest physiotherapy, inhaled medications, anti-inflammatory agents, optimization of nutrition, and exercise as tolerated.

Systemic antibiotics are the mainstay of therapy for an acute exacerbation. The severity of the infection dictates the route of administration. Mild exacerbations can be treated with oral antibiotics whereas severe exacerbations require the use of intravenous antibiotics. In general, the CF guidelines recommend using one antibiotic to cover each pathogenic bacteria and two antibiotics to cover *P. aeruginosa.*[93] Treatment with antipseudomonal antibiotics has demonstrated an improvement in pulmonary function tests, reduction in sputum bacterial density, and inflammatory markers.

The specific antibiotic selection should be patient-specific based on historic sputum culture and sensitivities and then narrowed or altered based on sputum cultures and sensitivities obtained at the onset of the exacerbation. Oral therapy with antipseudomonal coverage includes ciprofloxacin or levofloxacin. For moderate to severe exacerbations, an antibiotic combination of a beta-lactam along with either a fluoroquinolone or tobramycin should be used. If clinical response is inadequate after approximately five days of treatment, consideration should be given to switching the beta-lactam. Other alternatives may include switching the fluoroquinolone to tobramycin or exchanging tobramycin with amikacin. Colistimethate may also be an option when there is treatment failure.

The selection of antibiotic coverage for *S. aureus* will be dependent on if it is methicillin-sensitive or –resistant. Mild exacerbations with methicillin-sensitive *S. aureus* may be treated with trimethoprim-sulfamethoxazole, doxycycline, or amoxicillin-clavulanate. Trimethoprim-sulfamethoxazole and doxycycline may still be used for methicillin-resistant *S. aureus* in mild infections; however, severe exacerbations require the use of oral linezolid, intravenous vancomycin, or intravenous ceftaroline. When culture results reveal both *Pseudomonas* and *Staphylococcus*, a combination of the above agents is required. Due to the lack of sensitivity of ceftaroline against *P. aeruginosa* and the use of another beta-lactam for *Pseudomonas* coverage, ceftaroline is generally not encouraged in these situations in order to avoid using two beta-lactams simultaneously. In addition, the combination of piperacillin-tazobactam with vancomycin and tobramycin should be avoided due to the increased risk of renal toxicity.

Dosing of antibiotics in CF patients can be a challenge to ensure adequate lung penetration and maximum bactericidal activity. For instance, beta-lactam's effect is based upon time above the minimum inhibitory concentration whereas aminoglycosides and fluoroquinolones killing effect is dependent upon the peak antimicrobial tissue concentration along with the post-antibiotic effect. In addition, the pharmacokinetics of antibiotics in CF patients differ compared to most other individuals. The volume of distribution and total body clearance is increased in CF patients for hydrophilic drugs such as aminoglycosides, penicillins, and cephalosporins. Specifically, the aminoglycoside's initial dose is higher than the general population and adjusted based on patient-specific pharmacokinetic parameters. The CF guidelines also support the use of extended-interval dosing or once-daily dosing of aminoglycosides in patients with normal renal function. The recommended target peak concentration differs between once-daily dosing and conventional dosing. The target peak concentration for once-daily dosing is 20 to 30 mcg/mL (mg/L) versus the 8 to 12 mcg/mL (mg/L) for conventional dosing. The calculated concentration at 18 hours should be < 0.5 mcg/mL (mg/L) to minimize toxicity and to ensure at least a 6-hour period with low serum concentrations prior to the next dose.

Vancomycin, on the other hand, can be dosed and monitored in CF patients similar to the general population. The pharmacokinetics of vancomycin appears to be unaltered in CF patients. Patient-specific pharmacokinetic calculations should be used to maintain a trough concentration of 15 to 20 mcg/mL (mg/L; 10.4-13.8 µmol/L) in adults and 7 to 10 mcg/mL (mg/L; 4.8-6.9 µmol/L) in children. AUC-guided dosing may also be used instead of trough-drivien dosing.[94] A target AUC between 400 and 600 x h/L is suggested for adults and pediatric patients.

The duration of treatment for an acute exacerbation is not standardized. Some centers continue antibiotic regimens until the resolution of symptoms and others continue therapy until there are improvements in the FEV1. Typically, antibiotics are continued for 10 days to 3 weeks depending upon the clinical course.

Bone Disease

Bone disease is a common complication of CF and is characterized by low bone mineral density (BMD). Factors that may contribute to bone disease over time may include malabsorption of vitamin D, poor nutritional status, physical inactivity, glucocorticoid therapy, and delayed pubertal maturation. It is thought that loss of bone mass occurs in childhood and worsens around puberty. Puberty plays a role in bone development and peak bone accruals usually occur during the growth velocity. Delay can be seen in patients with poor nutrition and poor control of CF. Dual-energy x-ray absorptiometry (DXA) scans should be performed routinely on adults and children older than 8 years if they are less than 90% of their ideal body weight, their FEV1 is less than 50% (0.5) of predicted, they received systemic glucocorticoids for more than 90 days in the previous year, have delayed puberty, or a history of fracture.[95] Osteoporosis is defined as having a BMD T score > −2.5, and osteopenia with a score between −1 and −2.5. Low BMD is common among adults with CF. A T-score less than −1 has been observed in 85% of adult patients with CF. As much as 34% of adult CF patients have a Z score less than −2 and 10% have T-scores less than −2.5. In pediatric patients, osteopenia is found in up to 47% of patients and osteoporosis in up to 34% of patients. Z scores are typically used for children less than 18. T scores are not meaningful in children. Both T and Z scores are useful in patients 18 to 30 years of age and T scores should be used in those 30 years and older.

Strategies for preventing the loss of bone minerals in patients with CF include maintaining good lung function, treatment of pulmonary exacerbations in a timely manner, optimizing nutritional care, and promoting the maintenance of lean body mass. Oral and inhaled steroids should be avoided as much as possible. Weight-bearing activities and exercise are recommended. Vitamin D and calcium supplementation should be continued as directed by the Cystic Fibrosis Foundation guidelines. Specifically, vitamin D3 (cholecalciferol) should be supplemented to achieve and maintain serum 25-hydroxyvitamin D concentration of 30 to 60 ng/mL (75-150 nmol/L) along with 1300 to 1500 mg of calcium per day.

An area of active research includes the use of growth hormone (GH) in patients with CF. With the use of GH, improvement in height and bone mineral content has been demonstrated. Long-term studies are still in progress to determine the optimal management of GH in patients with CF.

If DXA T score is greater than −1 or Z score is greater than −2.0, fragility fractures have occurred, or a patient is awaiting transplant, or BMD loss is greater than 3% to 5% a year, bisphosphonates are indicated in these patients. If the T/Z score is less than or equal to 2.0 then bisphosphonates are indicated. Bisphosphonates have been studied in trials in adults with CF and trials have yet to be heavily studied in children with CF. Pamidronate resulted in gains in the lumbar spine and total hip after six months; however, there were significant adverse effects from bone pain, fever, and phlebitis in 75% of the patients, some of which required hospitalization. The IV bisphosphonate, zoledronic acid, showed benefit; however, the patient dropout rate was 20% due to bone pain.[96]

In patients aged 5 to 30 years old with CF and low BMD, oral alendronate, 5 mg/day and 10 mg/day based on weight, increased BMD by 16.5% and was well-tolerated.[97] Additionally, alendronate is the only bisphosphonate available in liquid formulation. Risedronate 35 mg once weekly in patients older than 18 with CF was found to improve lumbar spine BMD.[98] There were reports of bone pain in the first 56 days of risedronate use, with some leading to discontinuation of risedronate.

Denosumab is a monoclonal antibody that works to inhibit osteoclasts differentiation and activation and functions as an anti-resorptive therapy to reduce bone breakdown. It is approved for the treatment of osteoporosis in men and post-menopausal women and glucocorticoid-induced osteoporosis. There are no studies published evaluating the use of denosumab in patients with CF. Until more studies can be conducted denosumab is considered second-line for patients who cannot tolerate, have a contraindication, or fail bisphosphonate therapy.

There are other adverse effects to monitor when initiating an oral bisphosphonate such as esophageal ulcers, osteonecrosis, and hypocalcemia. IV bisphosphonates appear to have that acute-phase reaction after the initial infusion leading to flu-like symptoms but have been seen to be more severe in patients with CF for an unknown reason. A short course of NSAIDs or acetaminophen was found to mitigate the effect.

Long-term data is lacking for the safety of bisphosphonates in children and young adults, the general approach is to minimize bisphosphonate treatment to typically less than five years with periods of off treatment or bisphosphonate holidays.[99] Following this off-treatment period, patients may be monitored via DXA scans every 1 to 2 years to assess for interval bone loss. If no treatment is needed following a DXA scan, DXA scores may be repeated every 5 years unless there is a change in risk factors if T or Z scores are –1 or better. Individuals between –1 and –2 should have a repeat DXA every 2 to 4 years and annually for scores greater than –2.

Cystic Fibrosis–Related Diabetes

CFRD is the most common comorbidity in patients with CF, occurring in 20% of adolescents and 50% of adults. The course is progressive in nature, and patients may move back and forth between an impaired state and CFRD. Uncontrolled CFRD may correlate with pulmonary function decline, weight loss, and *P. aeruginosa*. This comorbidity is difficult to manage as patients are directed to have high caloric intake due to having CF. Diabetes ketoacidosis (DKA) is rare.[22] CFRD may present like in the honeymoon period when compared to type 1 diabetes patients because they may still have endogenous insulin secretion.

Following the diagnosis of CFRD, patients should be treated with insulin therapy instead of oral anti-hyperglycemic medications. Data suggests that therapies such as sulfonylureas, metformin, meglitinides, and thiazolidinediones are not as effective as insulin. After an acute illness or systemic glucocorticoid treatment, insulin requirements may increase and take about 4 to 6 weeks to return to baseline. Close monitoring is required to ensure that hypoglycemia does not occur in these patients following acute illness. Dosing for insulin is usually between 0.5 and 0.8 units/kg/day in both adolescents and adults. If a patient has fasting hyperglycemia a basal/bolus regimen is recommended. The starting dose for basal insulin is 0.125/units/kg and may be titrated up to 0.25/units/kg. For meal coverage doses start at 0.5 to 1 unit for every 15 grams of carbohydrates consumed. The doses may be titrated by 0.5 units per 15 grams of carbohydrates to achieve 2 hours post-prandial blood glucose. Carbohydrate counting is recommended to best determine a pre-meal insulin dose. Correction doses are typically 0.5 to 1 unit of rapid-acting insulin based on a insulin sensitivity factor of 1 unit for every 50 mg/dL (2.8 mmol/L) above 150 mg/dL (8.3 mmol/L). Some lifestyle recommendations differ in patients with CFRD when compared to patients with diabetes mellitus. Carbohydrate intake is individualized, there is no restriction on fat intake, protein intake is doubled, sodium intake is liberalized, and regular supplementation with ADEK vitamins is needed. Weight loss is not recommended.

Blood glucose (BG) should be self-monitored at least three times daily and goals should be individualized. Monitoring can also occur using a continuous glucose monitoring (CGM). Plasma glucose goals for CFRD are similar to patients with diabetes as recommended by ADA but some patients may benefit fromhigher or lower goals. Glucose monitoring may be useful to detect early glucose abnormalities that the OGTT and A1c cannot detect. While CGM's are not approved to diagnosis diabetes, they can be useful in detecting glucose excursions when titrating inulin therapy. The patient's A1c may falsely indicate good glycemic control despite the fact that the patient may have frequent hyperglycemia or hypoglycemia.[23] Like other patients with diabetes mellitus, the A1c treatment goal should be ≤ 7% (53 mmol/mol) to reduce the risk of microvascular complications; however goals must be individualized. An A1c should be ordered quarterly. Monitoring of microvascular complications such as nephropathy, retinopathy, and neuropathy is important. Screening for these complications should be initiated five years after diagnosis of CFRD.[22] The use of ACEI or ARBs are appropriate, and cough associated with ACEI use is seen in ~10% of patients. Nephropathy should be monitored using urine protein testing, with an albumin to creatinine ratio of 300 µg/mg (33.9 mg/mmol) or greater indicating macroalbuminuria and progression towards renal failure. Retinopathy is seen in 10% to 20% of patients with CFRD and should be monitored through regular dilated retinal exams. Neuropathy may be less severe in patients with CFRD but annual foot evaluations are still recommended. An annual lipid profile is recommended for patients with CFRD.

Cystic Fibrosis Liver Disease

Cystic fibrosis liver disease (CFLD) is the third leading cause of death among patients with CF.[21] There is a wide variety of presentations of liver disease from steatosis, cholelithiasis, and multilobular cirrhosis.

The aim of the treatment of CFLD is to prevent further liver damage and complications related to portal hypertension and cirrhosis. There is currently no long-term treatment that has proven efficacy; however, there are treatments for the complications of CFLD. Ursodiol displaces toxic bile from enterohepatic circulation, has a cytoprotective effect on cells that are exposed to toxic bile acids, stimulates Ca-activated chloride channels, and has immunoregulatory properties. It may delay the progression of cirrhotic changes in patients with CFLD. It is dosed 20 to 30 mg/kg/day. Table 47-5 for medical management of complications of CFLD. In patients with advanced CFLD with decompensated liver failure, transplantation is the treatment of choice.

TABLE 47-5

Medical Management of Complications Related to Cystic Fibrosis Liver Disease

Indication	Treatment of choice
Hepatic steatosis	Optimize nutritional status and evaluate for deficiencies of essential fatty acids, carnitine, and choline
Hepatic congestion	Optimize cardiopulmonary function
Cholestasis	Treatment of fat-soluble vitamin deficiency
Portal hypertension	Beta-blocker use with caution, variceal band ligation
Ascites	Salt restriction, or transjugular intrahepatic portosystemic shunt

Cystic Fibrosis GI Disease

Gastrointestinal complications have become a common cause of morbidity in the cystic fibrosis population and include conditions such as gastroesophageal reflux (GERD), constipation, distal intestinal obstruction syndrome, and fibrosing colonopathy along with others.

GERD in the CF patient is similar to that of the general population. Even though there has been some association between GERD and pulmonary disease, there is not overwhelming evidence to support a causal association, nor that treatment has a beneficial effect on pulmonary function. There are pros and cons to the management of GERD with proton pump inhibitors (PPIs) including improving fat absorption in patients with pancreatic insufficiency whereas potential harm would be the negative effects on bone health in a population already at increased risk for osteoporosis. A clear goal should be determined when initiating PPIs in cystic fibrosis patients with GERD and therapy discontinued if no improvement in symptoms is noted. Patients should be monitored for increased pulmonary exacerbations, vitamin B12 deficiency, hypomagnesemia, and bone health while receiving PPI treatment.

Constipation affects 25% to 50% of cystic fibrosis patients and is a common cause of flatulence and abdominal pain. Constipation in the CF patient results from abnormal intestinal fluid composition, dysmotility, and pancreatic insufficiency even though pancreatic sufficient patients have a relatively dehydrated bowel. Treatment generally consists of osmotic laxatives with or without electrolytes along with an assessment of the PERT dosing to ensure an adequate dose. Lubiprostone may be considered a second-line option in adult cystic fibrosis patients with severe refractory constipation.

Distal intestinal obstruction syndrome (DIOS) results from either a complete or incomplete obstruction of the ileocecum by thickened intestinal contents and is manifested by cramping abdominal pain, abdominal distention, flatulence, weight loss, and poor appetite. Unlike constipation which is a gradual onset of fecal impaction, DIOS occurs acutely to intermittently with symptoms becoming progressively more severe over time. DIOS is more common in those with pancreatic insufficiency and having the F 508 del genotype. Others at risk of DIOS include patients with poorly controlled malabsorption, dehydration, and opioid use. Treatment should target fluid and electrolyte abnormalities along with a regimen of either oral/nasogastric rehydration and osmotic laxatives or hyperosmolar enemas with or without laxatives. Prevention should be the goal once the impaction is removed by optimizing the pancreatic enzymes and sufficient hydration.

Fibrosing colonopathy, a dose-limiting side effect of pancreatic enzymes, is a severe intestinal process involving fibrosis and strictures. First detected in patients receiving large doses of pancreatic enzymes, pancreatic enzyme dosing recommendations now limit the maximum dose to 2,500 lipase units/kg/meal or 10,000 lipase units/kg/day. Adjunctive therapy with H2 blockers or proton pump inhibitors helps maintain the recommended dosing range while boosting the stability of the pancreatic enzymes in the acidic environment of the GI tract and increasing the efficiency of the prescribed pancreatic dose in managing the fat malabsorption.

Mental Health

Managing CF is complex and takes about 2 to 4 hours of the day, especially, if other complications arise which may increase this time. The burden of this disease may lead to patient and parent depression and anxiety. Depression prevalence ranges from 8% to 29% in children and adolescents and 13% to 33% in adults.[100,101] Similarly, 22% of the adolescent population and 32% of the adult population reported anxiety.[102] Reports of depression and anxiety have been associated with decreased lung function, lower body mass index, worse adherence, and worse health-related quality of life.[103] It is recommended by the Cystic Fibrosis Foundation that all children with CF who are 7 to 11 years old be assessed for depression and anxiety or when there is a concern for the child exhibiting symptoms of depression or anxiety by his/her team or caregivers. Annual screening for depression and anxiety is recommended for all individuals with CF beginning at 12 years of age utilizing the PHQ-9 and GAD-7. Screening is also recommended for caregivers.

When caring for patients with CF it is important to provide behavioral interventions to help alleviate distress when it relates to medical procedures. Additionally, to provide supportive intervention when PHQ/GAD scores are elevated. Patients who are aged 7 to 11 who present with clinically significant or elevated PHQ and GAD scores may undergo evidence-based psychological interventions such as cognitive-behavioral therapy (CBT) with continued monitoring. For those that are 12 years of age and older with mild symptoms of depression or anxiety, education can be provided, as well as preventative and supportive interventions and to continue to follow up at the next scheduled visit. For those 12 years of age and older with moderate symptoms it is appropriate to engage in CBT, if this treatment is not alleviating symptoms, psychotropic medication may be considered next. For those 12 and older, selective serotonin reuptake inhibitors (SSRIs) are recommended for the treatment of depression and anxiety. Doses of SSRIs may need to be increased when used in combination with lumacaftor. Additionally, linezolid is not recommended for use with SSRIs when alternatives are available. QTc prolongation may be more significant with the use of citalopram and may require EKG monitoring when used with other medications that may cause QT prolongation.

EVALUATION OF THERAPEUTIC OUTCOMES

CF patients are typically monitored every month for the first year after diagnosis and then every 1 to 3 months, depending on the stability of their illness. Clinicians should evaluate the patient’s pulmonary function and lung volumes using pulmonary function tests (PFTs) quarterly and assess for unusual or increased respiratory symptoms at each clinic visit to determine if the current pharmacotherapy regimen is effective. Quarterly sputum cultures are typically collected to determine which organisms are growing in the patient’s lungs. Airway clearance, inflammation, and bacterial colonization must be under control for optimal pulmonary function. Weight and height should be measured at every visit to assure adequate growth (pediatrics) and nutrition (pediatrics and adults). A BMI greater than the 50th percentile in children and greater than 22 in female adults and 23 in male adults is associated with optimal lung function. The pharmacist is integral to the multidisciplinary CF team to ensure optimization of pharmacotherapy and to evaluate and encourage patient/family adherence to recommended treatments, both nonpharmacologic and pharmacologic.

CONCLUSION

Cystic fibrosis is a multi-system disease requiring a multi-modal treatment approach administered through a multidisciplinary team to provide optimal care and the best patient outcomes. This multidisciplinary team consists of nurses, physicians, respiratory therapists, dietitians, social workers, and an overall program coordinator as required team members. The CF Foundation recommends that pharmacists, physical therapists, psychologists, and a research coordinator also be a part of these teams.

With the advancements in science and treatment options, not only is the quality of life for cystic fibrosis patients increasing but their overall lifespan is also expanding. Thus, it is crucial that the healthcare team optimizes treatment to reduce pulmonary exacerbations, delay colonization by pathogens and maintain lung health; maximizes adequate nutrition with appropriate dosing of pancreatic enzymes and vitamin supplementation; and initiates CFTR modulators to target the underlying pathology and advance the management of cystic fibrosis.

ABBREVIATIONS

ACT	Airway Clearance Technique
ADA	American Diabetes Association
ADEs	adverse drug events
ALT	alanine transaminase
AST	aspartate aminotransferase
BMD	bone mineral density
BMI	body mass index
CBAVD	congenital bilateral absence of the vas deferens
CBT	cognitive behavioral therapy
CF	cystic fibrosis
CGM	continuous glucose monitoring
CFLD	cystic fibrosis liver disease
CFMS	cystic fibrosis metabolic syndrome
CFRD	cystic fibrosis–related diabetes
CFTR	cystic fibrosis transmembrane conductance regulator
CMP	comprehensive metabolic panel
CPT	chest physical therapy
DIOS	distal Intestinal obstruction syndrome
DXA	dual-energy x-ray absorptiometry
EKG	electrocardiogram
FDA	food and drug administration
$FEF_{25\text{-}75}$	forced expiratory flow at 25% and 75%
FVC	forced vital capacity
FEV1	orced expiratory volume in 1 second

GAD-7	generalized anxiety disorder assessment
GERD	gastroesophageal reflux disease
GGTP	gamma-glutamyl transpeptidase
GGT	gamma-glutamyl transferase
GH	growth hormone
G-tube	gastrostomy tube
H2 Blockers	histamine 2 receptor antagonist
HTS	hypertonic saline
IRT	immunoreactive trypsinogen
MRSA	methicillin-resistant *Staphylococcus aureus*
OGTT	oral glucose tolerance test
PEP	positive expiratory pressure
PERT	pancreatic enzyme replacement therapy
PHQ-9	Patient Health Questionnaire
PI	pancreatic insufficiency
PIVKA II	protein induced by vitamin K absence-II
PPI	proton pump inhibitor
QTc	corrected QT interval
SMBG	self-monitoring blood glucose
SOCAP	subjective, objective, calculations, assessment plan note

SELF-ASSESSMENT QUESTIONS

1. Which of the following organisms is typically found earliest in respiratory cultures of patients with cystic fibrosis?

   A. *Staphylococcus aureus*

   B. *Pseudomonas aeruginosa*

   C. *Burkholderia cepacia*

   D. *Haemophilus Influenza*

2. What class of Mutation is Delta F508 (the most common mutation found in cystic fibrosis)?

   A. Class 2

   B. Class 3

   C. Class 5

   D. Class 6

3. Which tests is used to diagnose cystic fibrosis?

   A. Sweat Test

   B. Nasal potential difference

   C. Genetic testing

   D. All of the above

4. Which of the following BEST describes the genetic acquisition of cystic fibrosis?

   A. Only one parent is a carrier of the CF gene

   B. Only one grandparent is a carrier of the CF gene

   C. Both parents are carriers of the CF gene

   D. Cystic fibrosis is not acquired genetically

5. A 6-year-old patient is admitted for a pulmonary exacerbation. The patient typically grows methicillin-resistant *S. aureus* (MRSA) and Pseudomonas. Which of the following antibiotic regimens would be the best initial treatment?

   A. Nafcillin and tobramycin

   B. Vancomycin and ciprofloxacin

   C. Vancomycin Tobramycin and Ceftazidime

   D. Linezolid and Ceftazadime

6. You are seeing a 16-year-old CF patient for their yearly visit. While taking a history, the patient mentioned that she almost had an accident 3 nights ago as they were unable to see the oncoming car that merged into the lane. Which of the following should be the next step in evaluating this patient?

   A. refer to ophthalmology

   B. check vitamin levels

   C. perform vision screen in clinic

   D. check fecal elastase

7. Which of the following CFTR modulators is indicated in seven-year-old patients with only one delta F 508 mutation?

   A. Ivacaftor

   B. Elexacaftor/tezacaftor/ivacaftor

   C. Lumacaftor/ivacaftor

   D. Tezacaftor/ivacaftor

8. AA's family is thinking about initiating lumacaftor/ivacaftor. AA is four years old. What monitoring parameter is most appropriate to obtain prior to initiating lumacaftor/ivacaftor?

   A. Complete blood count

   B. DEXA scan

   C. Hearing exam

D. Liver function panel

9. BA is found to be indicated for pancreatic enzyme replacement therapy (PERT). BA weights 20 kg. Accounting for all of BA's meals and snacks, what is the max dose that should be prescribed for BA and their PERT therapy.

   A. 50,000 lipase units per meal and 25,000 lipase units per snack

   B. 20 lipase units per meal and 10 lipase units per snack

   C. 40,000 lipase units per meal and 10,000 lipase units per snack

   D. 40 lipase units per meal and 20 lipase units per snack

10. Which is the *most* appropriate treatment for a patient with CFRD with impaired glucose tolerance?

   A. Metformin

   B. Pioglitazone

   C. Insulin Glargine

   D. Insulin Aspart

11. When assessing a 13-year-old patient with CF who may have a high disease burden. This patient has anxiety involving their treatment as well the team has seen a decrease in lung function over the last year, lower BMI over the last year, and the patient has been skipping their treatments in the evening. This patient refuses a referral to a mental health professional. What is the most appropriate next treatment step for this patient?

   A. Initiate citalopram 40 mg daily

   B. Initiate CBT

   C. Initiate mirtazapine 15 mg nightly

   D. Initiate melatonin 5 mg nightly

12. The purpose of using hypertonic saline in a cystic fibrosis patient is to

   A. Decrease bacterial growth

   B. Decrease sweat chloride content

   C. Hydrate pulmonary secretions

   D. Increase serum sodium content

13. A cystic fibrosis patient is using the following inhaled medications:

   Cayston

   Hypertonic saline

   Albuterol

   Pulmozyme

   In what order should these medications be administered (listed first to last)?

   A. Cayston, Hypertonic saline, Albuterol, Pulmozyme

B. Pulmozyme, Albuterol, Hypertonic Saline, Cayston

C. Albuterol, Pulmozyme, Cayston, Hypertonic Saline

D. Albuterol, Hypertonic Saline, Pulmozyme, Cayston

E. Hypertonic Saline, Albuterol, Cayston, Pulmozyme

14. Chronic management of airway inflammation in cystic fibrosis should (typically) includes which of the following?

    A. Hypertonic Saline

    B. Aerosolized aztreonam

    C. Azithromycin

    D. Cholecalciferol

15. The Cystic Fibrosis Foundation recommends all individuals with cystic fibrosis maintain a serum 25-hydroxyvitamin D goal of at least ___________________ ng/mL.

    A. 15 (37 nmol/L)

    B. 30 (75 nmol/L)

    C. 60 (150 nmol/L)

    D. 90 (225 nmol/L)

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Haemophilus influenza. The patient is typically colonized with *Staphylococcus aureus* second and non-mucoid pseudomonas after that. *Burkholderia cepacia* is typically found in older patients with more advanced lung disease.

2. **A.** class 2 mutations occur when the mutant protein is made in its entirety but fails to fold properly inside the cell, This results in the absence of mature CFTR in the cellular membrane to perform its specific chloride ion conductance function.

3. **D.** Sweat test is still the gold standard all can be used in the diagnosis of CF. Genetic testing is used to determine the patient's specific mutations and is helpful in determining which modulators the patient will qualify for. Nasal potential difference provides evidence of the abnormal function of the cystic fibrosis transmembrane conductance regulator as values less than −40 mV is abnormal.

4. **C.** Cystic Fibrosis occurs in a classic single-gene (Mendelian) autosomal recessive pattern. Autosomal recessive patterns of inheritance require both parents to be carriers of the gene.

5. **C.** Nafcillin does not typically cover methicillin-Resistant staph aureus. Vancomycin is one preferred IVC treatment for MRSA. Ciprofloxacin is typically reserved for outpatient therapy, as it is one of the few oral antibiotics that can treat pseudomonas. Pseudomonas is typically treated with 2 antibiotics to decrease the development of antibiotic resistance.

6. **B.** pancreatic insufficiency causes decreased absorption of fats and which then leads to malabsorption of fat-soluble vitamins. In a 16-year-old patient, symptoms would be likely related to suboptimal adherence to vitamin therapy as opposed to malabsorption. An early symptom of vitamin A deficiency is night blindness. Vitamin E can cause neurologic deficits, Vitamin K clotting disorders and easy bleeding, and Vitamin D rickets

7. **B.** Is the only CFTR modulator agent that is indicated for patients six and older with at least one delta F 508 mutation.

8. **D.** When initiating a CFTR modulator it is important to assess baseline transaminases such as ALT and AST as well as obtaining an eye exam in pediatric patients.

9. **A.** The maximum dose per meal is 2,500 lipase units per kilogram per meal with snacks being half the dose at mealtimes.

10. **D.** Due to patients with CFRD having multimodal reasons for impaired glucose tolerance. CFRD may be related to a loss of insulin-producing islet cells due to autolysis and fatty infiltration of the pancreas. As this is not a process due to entirely glucose resistance processes large doses of aspart may not be needed with impaired postprandial glucose. Insulin is usually the most appropriate treatment for CFRD, however, a patient's fasting glucose becomes impaired later in disease progression whereas prandial glucose is affected earlier on therefore not requiring insulin glargine initially.

11. **C.** May help with weight gain as well as anxiety and depression symptoms. Initiating citalopram may put the patient at QT prolongation. The patient is refusing counseling at this time and melatonin may not help with anxiety.

12. **C.** Hypertonic saline acts as an osmotic agent which draws water into luminal secretions resulting in the restoration of airway hydration. It is a solution possessing an osmotic pressure greater than that of a physiologic isotonic salt solution (0.9%NaCl). By drawing water from CFTR defective airway epithelial cells, the periciliary layer becomes rehydrated and mucociliary clearance reestablished.

13. **D.** Bronchodilators will open the airways and make it easier to expel mucus and allow medications to penetrate deeper into the lung. Hypertonic saline will mobilize the mucus and improve airway clearance by hydrating the airways. Pulmozyme will thin the mucus. All of these agents work to open and clear the airways of mucus allowing the inhaled antibiotics to work on the remaining bacteria.

14. **C.** Azithromycin has demonstrated benefits in CF patients with chronic infection with *P. aeruginosa*. These benefits do not appear to be exclusively related to its antimicrobial effects but also an anti-inflammatory effect. The antimicrobial effects center around the ability of macrolides to reduce the ability of *Pseudomonas* to produce biofilms whereas the anti-inflammatory effect relates to azithromycin's ability to suppress the excessive inflammatory response noted in CF patients.

15. **B.** Vitamin D deficiency is probably the most commonly studied vitamin deficiency in CF patients and appears to have an impact on inflammation and maintenance of bone health. The cystic fibrosis foundation has guidelines specifically for vitamin D to ensure that the serum 25-hydroxyvitamin D levels remain at least at 30ng/mL (75 nmol/L) or higher in all patients with cystic fibrosis.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 50: Gastroesophageal Reflux Disease

Dianne May; Devin L. Lavender; Satish S.C. Rao

KEY CONCEPTS

KEY CONCEPTS

① Gastroesophageal reflux disease (GERD) can be described on the basis of either esophageal symptoms or esophageal tissue injury. The common symptoms include heartburn, regurgitation, chest pain, and dysphagia.

② Endoscopy is commonly used to evaluate mucosal injury from GERD and to assess for the presence of Barrett's esophagus or other complications, such as strictures or adenocarcinoma.

③ Whereas ambulatory reflux monitoring only measures acid reflux, combined impedance–pH monitoring measures both acid and nonacid reflux.

④ The goals of GERD treatment are to alleviate symptoms and improve health-related quality of life, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.

⑤ GERD treatment is determined by disease severity and includes: (a) lifestyle changes and patient-directed therapy with antacids, nonprescription H2-receptor antagonists (H2RAs), and/or nonprescription proton pump inhibitors; (b) pharmacologic treatment with prescription-strength acid suppression therapy; (c) surgery; and (d) endoscopic therapies.

⑥ Patients with typical GERD symptoms should be treated with lifestyle modifications as appropriate and a trial of empiric acid suppression therapy. Those who do not respond to empiric therapy or who present with alarm symptoms such as dysphagia, weight loss, or gastrointestinal (GI) bleeding should undergo endoscopy.

⑦ Surgical intervention is a viable alternative treatment for select patients when long-term pharmacologic management is undesirable or when patients have complications.

⑧ Acid suppression is the mainstay of GERD treatment. Proton pump inhibitors provide the greatest symptom relief and the highest healing rates, especially for patients with erosive disease or moderate-to-severe symptoms or with complications.

⑨ Many patients with GERD will relapse if medication is withdrawn; so, long-term maintenance treatment may be required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate-to-severe GERD, erosive disease, or other complications such as Barrett’s esophagus.

⑩ Patient medication profiles should be reviewed for drugs that may aggravate GERD. Patients should be monitored for adverse drug reactions and potential drug–drug interactions. Deprescribing PPIs or tapering to the lowest effective dose is a key strategy in preventing adverse effects.

BEYOND THE BOOK

BEYOND THE BOOK

Watch video entitled, “GERD” in AccessPharmacy. This ~6-minute video summarizes the normal function of the esophagus and stomach compared to that seen with acid reflux, complications of GERD, process of acid production, and pharmacologic therapy for GERD. Students' understanding regarding the Collect, Assess, and Plan steps of the Patient Care Process are addressed with this video.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common medical disorder.[1] GERD has been described based on its physiological, functional, and symptomatic attributes.[2,3] The Lyon consensus highlighted the physiological attributes of GERD, such as esophageal motor dysfunction and esophageal permeability issues. However, these abnormalities are nonspecific for GERD. The Rome IV conference described the functional syndromes with GERD characteristics. However, reflux causality cannot be made based on clinical presentation mimicking GERD.[2] The Montreal consensus defines GERD as “symptoms or complications resulting from refluxed stomach contents into the esophagus or beyond, into the oral cavity (including the larynx) or lung.”[1] The key is that these troublesome symptoms, defined as symptoms occurring twice weekly or more, is that they adversely affect the well-being of the patient.[4] Episodic heartburn that is not frequent enough or painful enough to be considered bothersome by the patient is not included in this definition of GERD.

GERD can be further classified as either symptom-based or tissue injury–based depending on how the patient presents.[1] Symptom-based GERD may exist with or without esophageal injury, and most commonly presents as heartburn, regurgitation, or dysphagia (difficulty swallowing). Less commonly, odynophagia (painful swallowing), water brash, belching, bloating, or hypersalivation may also occur. The absence of tissue injury or erosions is commonly termed nonerosive reflux disease (NERD). The presence of abnormal acid exposure on ambulatory reflux monitoring differentiates NERD from functional heartburn where no abnormalities are seen.[5] NERD should also be differentiated from reflux hypersensitivity where patients have physiologic (normal) acid production but are symptomatic. Functional heartburn or reflux hypersensitivity may not respond well to acid suppression therapy since the underlying cause is not acid related.

Tissue injury-based GERD may exist with or without symptoms. The spectrum of injury includes esophagitis (inflammation of the lining of the esophagus), Barrett's esophagus (when tissue lining the esophagus is replaced by tissue similar to the lining of the intestine), esophageal strictures, and esophageal adenocarcinoma.[1] Esophagitis occurs when the esophagus is repeatedly exposed to refluxed gastric contents for prolonged periods of time.[1] This can progress to erosion of the squamous epithelium of the esophagus (erosive esophagitis). Esophagitis is classified as low grade (grade A or B) or high grade (grade C or D) based on the Los Angeles classification system. Complications of long-term reflux may include the development of esophageal strictures, Barrett's esophagus, or possibly adenocarcinoma of the esophagus.

Gastroesophageal reflux symptoms associated with disease processes in organs other than the esophagus are referred to as extraesophageal reflux syndromes. Patients with extraesophageal reflux syndromes may present with chest pain, hoarseness, chronic cough, or asthma. An association between these syndromes and GERD should only be considered when they occur along with esophageal GERD syndrome because these extraesophageal symptoms are nonspecific and have many other causes.[1]

Many patients suffering from mild GERD do not go on to develop erosive esophagitis and are often managed with lifestyle changes, antacids, and nonprescription histamine-2 receptor antagonists (H2RAs) or nonprescription proton pump inhibitors (PPIs). Those with more severe symptoms (with or without tissue injury) predictably follow a course of relapsing disease, requiring more intensive treatment with acid suppression therapy followed by long-term maintenance therapy. Periodic assessment is important to assure the lowest effective medication dose is being used. Antireflux surgery offers an alternative for select patients in whom prolonged medical management is undesirable, those with refractory GERD, or those with complications. Bariatric surgery may be an option in obese patients. Endoscopic therapies continue to be evaluated in an effort to find a less invasive alternative therapy that bridges the gap between pharmacologic management and more invasive surgery.

EPIDEMIOLOGY

GERD occurs most commonly in those older than 50 years of age.[6] Although mortality is rare, GERD may have a significant economic impact and decrease the quality of life. The true prevalence of GERD is difficult to assess because many patients do not seek medical treatment, symptoms do not always correlate well with the severity of the disease, and there is no standardized definition or universal gold standard method for diagnosing the disease. However, the prevalence has risen significantly over the last 20 years with approximately 20% of adults in the United States suffering from GERD symptoms on a weekly basis.[7–9] The prevalence of GERD varies depending on the geographic region.[7,8] Over 50% of those taking a PPI still had persistent symptoms.[9]

Two contributing factors for the increased prevalence of GERD in females include pregnancy and the presence of NERD.[10] The prevalence of erosive esophagitis is higher in men.[10] Gender is an important factor in the development of Barrett's esophagus and esophageal adenocarcinoma, which are both more common in men. As such, screening for Barrett’s esophagus is only considered in men, except in unique circumstances, such as women with scleroderma and esophageal involvement.[11] Adenocarcinoma of the esophagus is more common in those with chronic GERD symptoms than those who do not have GERD. The relationship of adenocarcinoma with Barrett's esophagus, or long-standing GERD symptoms (as an independent risk factor for esophageal adenocarcinoma), remains to be clearly defined.

Established risk factors that may contribute to the development or worsening of GERD symptoms include obesity, tobacco smoking, and genetic predisposition.[12] Obesity is associated with a 2.5 times increased risk for developing GERD.[13] Tobacco smoking may increase the prevalence of GERD 1.26 times compared to nonsmokers.[6] Other risk factors or comorbidities for GERD include alcohol consumption, certain medications and foods, respiratory diseases, and reflux chest pain syndrome. More recently, nonalcoholic fatty liver disease and major depressive disorder have been reported as worsening GERD symptoms.[14]

PATHOPHYSIOLOGY

The key factor in the development of GERD is the abnormal reflux of gastric contents from the stomach into the esophagus, oral cavity, and/or the lung.[1] An incompetent antireflux barrier at the esophagogastric junction (EGJ) plays a major role in GERD pathophysiology.[3] In some cases, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function (Fig. 50-1). Patients may have decreased gastroesophageal sphincter pressures related to (a) spontaneous transient LES relaxations (TLESRs), (b) transient increases in intra-abdominal pressure, or (c) an atonic LES, all of which may lead to the development of gastroesophageal reflux. Problems with other normal mucosal defense mechanisms, such as abnormal esophageal anatomy, improper esophageal clearance of gastric fluids, reduced mucosal resistance to acid, delayed or ineffective gastric emptying, inadequate production of epidermal growth factor, and reduced salivary buffering of acid, may also contribute to the development of GERD. Substances that may promote esophageal damage on reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Thus, the composition and the volume of the refluxate, as well as duration of exposure, are important aggressive factors in determining the consequences of gastroesophageal reflux.

FIGURE 50-1

Normal versus weak lower esophageal sphincter pressure and relaxations via high-resolution manometry.

The presence of an “acid pocket” is a potential explanation for postprandial reflux symptoms and may represent a target for treatment of reflux disease. While gastric acidity is buffered by food, ambulatory pH reflux monitoring has shown that this buffering effect may vary in different parts of the stomach and esophagus. The acid pocket is thought to be an area of unbuffered acid in the proximal stomach that accumulates after a meal and may contribute to GERD symptoms postprandially.[15] It occurs due to meal-stimulated acid not mixing well with the chyme in the proximal stomach.

Gastric secretions form a distinct layer above the chyme. GERD patients are predisposed to upward migration of acid from the acid pocket. In addition, the acid pocket may also be positioned above the diaphragm in patients, especially in those with hiatal hernia, which increases the risk for acid reflux.

Lower Esophageal Sphincter Pressure

The LES is a specialized thickening of the smooth muscle lining of the distal esophagus with an elevated basal resting pressure.[13] The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach, but relaxes on swallowing to permit the passage of food into the stomach. There are three mechanisms by which defective LES pressure may cause gastroesophageal reflux. First, and probably most importantly, reflux may occur following spontaneous TLESRs that are not associated with swallowing. Although the exact mechanism is unknown, esophageal distension, vomiting, belching, and retching cause relaxation of the LES. While not thought to contribute significantly to erosive esophagitis, these transient relaxations, which are normal postprandially, may play an important role in symptom-based esophageal reflux syndromes. Transient decreases in sphincter pressure are responsible for more than half of the reflux episodes in patients with GERD. The propensity to develop gastroesophageal reflux secondary to transient decreases in LES pressure is probably dependent on numerous factors, including the degree of sphincter relaxation, efficacy of esophageal clearance, patient position (more common in recumbent position), gastric volume, and intragastric pressure. Second, reflux may occur following transient increases in intra-abdominal pressure (stress reflux). An increase in intra-abdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux. Third, the LES may be atonic, thus permitting free reflux as seen in patients with scleroderma.

Various foods and medications may aggravate esophageal reflux by decreasing LES pressure or by precipitating symptomatic reflux by direct mucosal irritation (Table 50-1). Pregnancy is a condition in which reflux is common. There are many postulated reasons for the increased incidence of heartburn during pregnancy, including hormonal effects on esophageal muscle, LES tone, and physical factors (increased intra-abdominal pressure) resulting from an enlarging uterus. A decrease in LES pressure resulting from any of the previously mentioned causes is not always associated with gastroesophageal reflux. Likewise, individuals who experience decreases in sphincter pressures and subsequently reflux do not always develop GERD. The other natural defense mechanisms (anatomic factors, esophageal clearance, mucosal resistance, and other gastric factors) must be evoked to explain this phenomenon.

TABLE 50-1

Foods and Medications That May Worsen GERD Symptoms

Foods/Beverages	Medications
Decreased Lower Esophageal Sphincter Pressure	
Fatty meal	Anticholinergics
Carminatives (peppermint, spearmint)	Barbiturates
Chocolate	Caffeine
Coffee, cola, tea	Dihydropyridine calcium channel blockers
Garlic	Dopamine
Onions	Estrogen
Chili peppers	Nicotine
Alcohol	Nitrates
	Progesterone
	Tetracycline
	Theophylline
Direct Irritants to the Esophageal Mucosa	
Spicy foods	Aspirin
Orange juice	Bisphosphonates
Tomato juice	Nonsteroidal anti-inflammatory drugs
Coffee	Iron
Tobacco	Quinidine
	Potassium chloride

Anatomic Factors

Disruption of the normal anatomic barriers by a hiatal hernia (when a portion of the stomach protrudes through the diaphragm into the chest) was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Now it appears that a more important factor related to the presence or absence of symptoms in patients with hiatal hernia is the LES pressure. Patients with hypotensive LES pressures and large hiatal hernias are more likely to experience gastroesophageal reflux following abrupt increases in intra-abdominal pressure compared with patients with a hypotensive LES and no hiatal hernia.

Esophageal Clearance

In many patients with GERD, the problem is not that they produce too much acid but that the acid spends too much time in contact with the esophageal mucosa. Contact time is dependent on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intraesophageal pH. In addition, swallowing is decreased during sleep, making nocturnal GERD a problem in many patients.

Mucosal Resistance

Within the esophageal mucosa and submucosa, there are mucus-secreting glands that may contribute to the protection of the esophagus. Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis. In theory, mucosal resistance may be related not only to esophageal mucus but also to tight epithelial junctions, epithelial cell turnover, nitrogen balance, mucosal blood flow, tissue prostaglandins, and the acid–base status of the tissue. Saliva is also rich in epidermal growth factor, stimulating cell renewal.

Gastric Emptying/Increased Intra-abdominal Pressure

Delayed gastric emptying can contribute to gastroesophageal reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Gastric volume is related to the volume of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Fatty foods may increase postprandial gastroesophageal reflux by increasing gastric volume, delaying the gastric emptying rate, and decreasing the LES pressure. Patients with gastroesophageal reflux, particularly infants, may have a defect in gastric antral motility. The delay in emptying may promote regurgitation of feedings, which might, in turn, contribute to two common complications of GERD in infants (eg, failure to thrive and pulmonary aspiration).[16]

Increased GERD symptoms and complications occur in obese patients. Obesity is considered an independent risk factor for GERD due to increased intra-abdominal pressure and reduced LES pressure.[17] An increased risk for developing both erosive esophagitis and Barrett's esophagus can be attributed to obesity. A gain in body mass index (BMI) of greater than 3.5 kg/m^2 is associated with increased new-onset GERD symptoms, regardless of baseline BMI.[18] TLESRs, incompetent LES, and impaired esophageal motility have been attributed to obesity.[19,20]

Composition of Refluxate

The composition, pH, and volume of the refluxate are important aggressive factors in determining the consequences of gastroesophageal reflux. If the pH of the refluxate is less than 2, esophagitis may develop secondary to protein denaturation. In addition, pepsinogen is activated to pepsin at this pH and may also cause esophagitis. Duodenogastric reflux esophagitis, or “alkaline esophagitis,” refers to esophagitis induced by the reflux of bilious and pancreatic fluid. The term “alkaline esophagitis” may be a misnomer in that the refluxate may be either weakly alkaline or acidic in nature. Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. Specifically, the percentage of time that the esophageal pH is less than 4 is greater for patients with severe disease as compared with that for patients with mild disease. Nevertheless, the combination of acid, pepsin, and/or bile is a potent refluxate in producing esophageal damage.

The pathophysiology of gastroesophageal reflux is a complex cyclic process. It is difficult, if not impossible, to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing or an incompetent LES pressure leading to gastroesophageal reflux. Understanding the factors associated with the development of GERD provides insight into the treatment modalities currently used to manage patients suffering from this disease.

Complications

Several complications may occur with gastroesophageal reflux, including esophagitis, esophageal strictures, Barrett's esophagus, and esophageal adenocarcinoma. Strictures are common in the distal esophagus and are 1 to 2 cm in length. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin is an additional risk factor that may contribute to the development or worsening of GERD complications. In some patients, the reparative process leads to the replacement of the squamous epithelial lining of the esophagus by specialized columnar-type epithelium (Barrett's esophagus), which increases the incidence of esophageal strictures by as much as 30%. Screening for Barrett's esophagus is indicated in men with chronic GERD symptoms (more than 5 years) and/or heartburn or acid regurgitation occurring at least weekly; and two or more of the following risk factors for Barrett's esophagus or esophageal adenocarcinoma: (1) over 50 years old; (2) White race; (3) central obesity (waist circumference greater than 102 cm or waist-hip ratio greater than 0.9); (4) tobacco use (current or previous use); and (5) family history of Barrett's esophagus or esophageal adenocarcinoma.[21] Women with scleroderma and esophageal involvement may also benefit from screening for Barrett’s esophagus.[11] The risk of esophageal adenocarcinoma may be higher for patients with Barrett's esophagus as compared with that for the general population. The annual risk of esophageal adenocarcinoma was 0.2% to 05% in those with nondysplastic Barrett's esophagus.[21] The annual risk of cancer progression increases to 0.7% in those with low-grade dysplasia and as high as 7% in those with high-grade dysplasia.[14,21]

Helicobacter pylori

The role of *H. pylori* status for patients with GERD is uncertain. As a consequence of the controversy surrounding *H. pylori* and GERD, specific guidelines on how to handle patients who are *H. pylori* positive are lacking. Most clinicians would probably opt to eradicate *H. pylori* infections once detected. However, routine screening for *H. pylori* is not recommended as part of the diagnosis and management of GERD. Further studies are needed to determine the role of *H. pylori* for patients with GERD.

CLINICAL PRESENTATION

Clinical Presentation: GERD

① GERD can be described on the basis of either esophageal symptoms or esophageal tissue injury. The common symptoms include heartburn, regurgitation, chest pain, and dysphagia. Dysphagia and odynophagia are considered alarm symptoms that require further evaluation. The severity or frequency of the symptoms of gastroesophageal reflux does not always correlate with the degree of esophageal tissue injury, but it does correlate with the duration of reflux. The clinical presentation of GERD overlaps with other conditions such as eosinophilic esophagitis, functional heartburn, and gastroparesis leading to challenges in managing GERD patients.[7] Reflux hypersensitivity may contribute to the patient's perception of symptom severity despite normal esophageal reflux exposure.[15] It is important to distinguish GERD symptoms from those of other diseases.

Diagnostic Tests

The most useful tool in the diagnosis of gastroesophageal reflux is the clinical history, including presenting symptoms and associated risk factors.[1] Patients presenting with typical symptoms of reflux, such as heartburn or regurgitation, do not usually require invasive esophageal evaluation. These patients benefit from an initial empiric trial of acid suppression therapy. A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy.[1] However, response to an empiric course of PPI was only 71% sensitive and 44% specific as compared to the combination of endoscopy and ambulatory pH monitoring.[22] This is due to the diverse symptom profile seen in GERD with variable responses to PPIs. PPIs are the most effective in patients with erosive esophagitis and are less effective with regurgitation, extraesophageal symptoms, gastroparesis, achalasia, eosinophilic esophagitis, reflux hypersensitivity, or functional gastrointestinal (GI) disorders. A strategy based on symptom domain and assessment of esophageal function testing may better define therapy.[23] The presence of erosive esophagitis (grade B, C, or D) or Barrett's esophagus per endoscopy, or abnormal pH testing defines “proven” GERD.[24] In addition having a “proven” diagnosis of GERD helps limit PPI use to those who are most likely to respond and avoid unnecessary adverse effects such as renal failure, enteric infections, vitamin/mineral deficiencies, bone fractures, and hypomagnesemia.[22,23] Proven GERD should be established before long-term acid suppression therapy is considered. In the case of functional heartburn, eosinophilic esophagitis, reflux hypersensitivity, or other nonreflux GI disorders, acid suppression therapy may not be the most appropriate choice for treatment as these are not acid-related disorders.

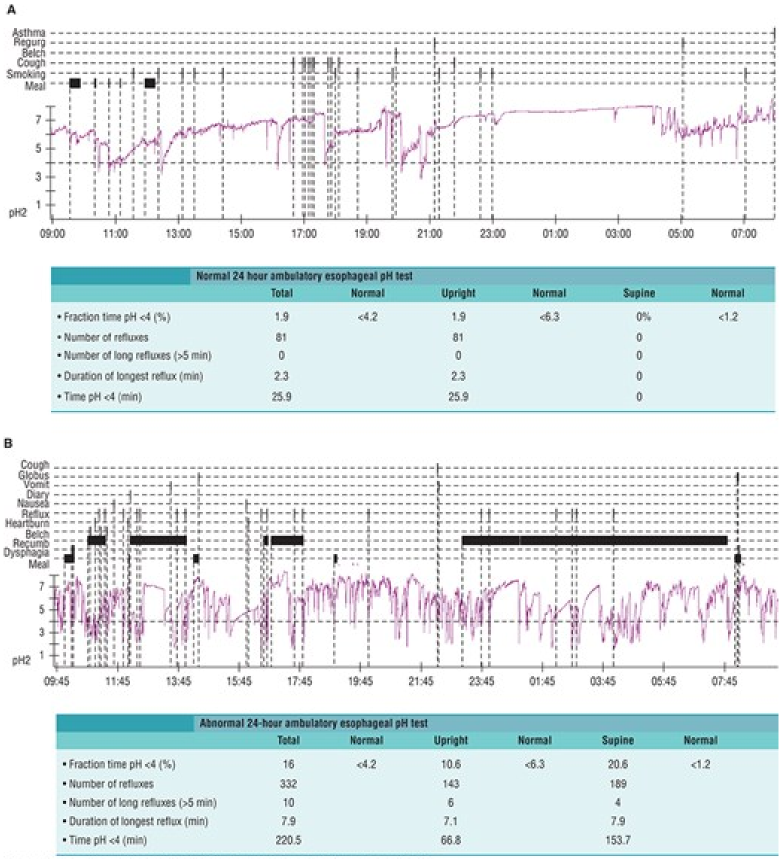
Diagnostic evaluation is useful to prevent misdiagnosis, identify complications, and assess treatment failures.[20] Diagnostic tests should be performed in those patients who do not respond to therapy and in those who present with alarm symptoms (eg, dysphagia, odynophagia, and weight loss), which may be more indicative of complicated disease. Additional diagnostic testing can help stratify patients with GERD into management categories that help guide clinicians to the most appropriate therapy.[24]

② Useful diagnostic tests for GERD include upper endoscopy, ambulatory reflux (pH) monitoring, combined impedance–pH monitoring, manometry/high-resolution esophageal pressure topography, and impedance manometry. Endoscopy is commonly used to evaluate mucosal injury and to assess for the presence of Barrett's esophagus or other complications, such as strictures or adenocarcinoma. Biopsies are necessary to diagnose Barrett's esophagus. A camera-containing capsule swallowed by the patient offers visualizing the esophageal mucosa via endoscopy. This is less invasive than traditional endoscopy and takes less than 15 minutes to perform in the clinician's office, but biopsies cannot be obtained. Unfortunately, the presence or absence of mucosal damage does not prove whether the patient's symptoms are reflux related; for that, ambulatory reflux monitoring is useful.

③ Whereas ambulatory reflux monitoring (24-hour pH monitoring) only measures acid reflux, combined impedance–pH monitoring measures both acid and nonacid reflux. Ambulatory reflux monitoring is performed by passing a small pH probe transnasally and placing it approximately 5 cm above the LES. Patients are asked to keep a diary of symptoms that later are correlated with the pH measurement corresponding to the time the symptom was reported (Fig. 50-2). Approximately 24 hours of data can be obtained using this method. The wireless pH monitoring involves attaching a radiotelemetry capsule to the esophageal mucosa. The advantages of this method are that a longer period of monitoring is possible (48-96 hours), it may demonstrate superior recording accuracy compared with some catheter designs, and it is more comfortable for the patient because a nasogastric tube is unnecessary.[1,22] Ambulatory reflux monitoring is especially useful in patients with symptoms that are refractory to PPIs.[25]

FIGURE 50-2

Graphical representation of a normal 24-hour esophageal pH test profile compared to an abnormal 24-hour ambulatory esophageal pH test profile.



Normal 24 hour ambulatory esophageal pH test	Total	Normal	Upright	Normal	Supine	Normal
• Fraction time pH <4 (%)	1.9	<4.2	1.9	<6.3	0%	<1.2
• Number of refluxes	81		81		0	
• Number of long refluxes (>5 min)	0		0		0	
• Duration of longest reflux (min)	2.3		2.3		0	
• Time pH <4 (min)	25.9		25.9		0	

Abnormal 24-hour ambulatory esophageal pH test	Total	Normal	Upright	Normal	Supine	Normal
• Fraction time pH <4 (%)	16	<4.2	10.6	<6.3	20.6	<1.2
• Number of refluxes	332		143		189	
• Number of long refluxes (>5 min)	10		6		4	
• Duration of longest reflux (min)	7.9		7.1		7.9	
• Time pH <4 (min)	220.5		66.8		153.7

Clinical Presentation: GERD Syndromes

Symptom-Based GERD Syndromes (With or Without Esophageal Tissue Injury)

[1,22,26–28] Typical symptoms (may be aggravated by activities that worsen gastroesophageal reflux such as recumbent position, bending over, or eating a meal high in fat):

- Heartburn (hallmark symptom described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck; may be waxing and waning in character)
- Regurgitation/belching
- Reflux chest pain

Alarm symptoms (these symptoms may be indicative of complications of GERD such as Barrett's esophagus, esophageal strictures, or esophageal adenocarcinoma and require further diagnostic evaluation):

- Dysphagia (common)
- Odynophagia
- Bleeding
- Weight loss

Tissue Injury-Based GERD Syndromes (With or Without Esophageal Symptoms)

Symptoms (may present with alarm symptoms such as dysphagia, odynophagia, or unexplained weight loss):

- Esophagitis
- Esophageal strictures
- Barrett's esophagus
- Esophageal adenocarcinoma

Extraesophageal GERD Syndromes

These symptoms have an association with GERD, but causality should only be considered if a concomitant esophageal GERD syndrome is also present:

- Chronic cough
- Laryngitis
- Wheezing
- Asthma (~50% with asthma have GERD)

Diagnostic Tests For GERD

Clinical History

- Used to make a clinical diagnosis of GERD in patients with typical symptoms.

Endoscopy

- Preferred for assessing mucosal injury and complications. Biopsies are needed to identify Barrett's esophagus, adenocarcinoma, and eosinophilic esophagitis (a nonacid-related esophageal disorder that does not respond well to acid suppression therapy).
- Indications for endoscopy: (1) persistent or progressive GERD symptoms despite appropriate therapy; (2) presence of dysphagia or odynophagia; (3) unexplained weight loss of more than 5%; (4) presence of GI bleeding and strictures; (5) screening for Barrett's esophagus in high-risk patients; (6) placement of wireless pH monitoring; (7) prior to endoscopic or surgical antireflux procedures or after procedures in those with recurrent symptoms.[26]
- Note: Noninflammatory GERD and major motor disorders may be missed by endoscopy.

Ambulatory Reflux Monitoring With or Without Impedance

- Useful for (a) patients not responding to acid suppression therapy when endoscopy is normal; (b) those with atypical/extraesophageal symptoms; or (c) those contemplating surgery.
- Assesses the acid exposure time (AET) and frequency of reflux episodes and helps determine if symptoms are acid-related.
    - An AET of less than 4% is considered normal, while greater than 6% is considered abnormal.[22]
    - Less than 40 reflux episodes in a 24-hour period is considered normal, while more than 80 reflux episodes per 24-hour period is considered abnormal.
- Reflux hypersensitivity is defined as positive symptom association in the absence of breakthrough acid.[27]
- Monitoring without impedance measures only acid reflux; adding impedance measures both acid and nonacid reflux
    - Testing patients off PPI therapy is recommended (1) to evaluate the AET in patients with normal endoscopy or low-grade esophagitis and no previously positive pH testing and (2) in those considering antireflux surgery.[22]
    - Testing patients on double-dose PPI therapy is recommended in patients with (1) prior Los Angeles grade C or D esophagitis; (2) long segment Barrett's esophagus; or (3) prior abnormal ambulatory pH monitoring. In these cases, pH–impedance monitoring is recommended to correlate refractory symptoms with reflux episodes or to identify inadequate acid suppression.

Manometry/High-Resolution Esophageal Pressure Topography

- Useful in those who have failed twice-daily PPI therapy with normal endoscopic findings to identify motor disorders, to evaluate peristaltic function in those who are candidates for antireflux surgery, and to assure proper placement of pH probes. Tubeless pH monitoring using endoscopic landmarks for placement may negate the need for manometry for ensuring proper placement of esophageal pH probes.

Impedance Manometry

- Evaluates bolus transit esophageal clearance/retention.
- Evaluates LES and UES pressures and peristalsis.

Empiric Proton Pump Inhibitor as a Diagnostic Test for GERD

- Less expensive and more convenient than ambulatory reflux monitoring but lacks standardized dosing regimen and duration of the diagnostic trial. This is not recommended as a diagnostic tool.

Barium Radiography

- Not routinely used to diagnose GERD because it lacks sensitivity and specificity; cannot identify Barrett's esophagus. Can detect hiatal hernia.

TREATMENT

Therapeutic modalities used in the treatment of gastroesophageal reflux are targeted at reversing the various pathophysiologic abnormalities.

Desired Outcomes

④ The goals of treatment are to (a) alleviate or eliminate the patient's symptoms and improve health-related quality of life, (b) decrease the frequency or recurrence and duration of gastroesophageal reflux, (c) promote healing of the injured mucosa, and (d) prevent complications. Therapy is directed at augmenting defense mechanisms that prevent reflux and/or decrease the aggressive factors that worsen reflux or mucosal damage. Therapy is directed at (a) decreasing the acidity of the refluxate, (b) decreasing the gastric volume available to be refluxed, (c) improving gastric emptying, (d) increasing LES pressure, (e) enhancing esophageal acid clearance, and (f) protecting the esophageal mucosa.

General Approach to Treatment

⑤ GERD treatment is determined by disease severity and includes: (a) lifestyle changes and patient-directed therapy with antacids, nonprescription H2RAs, and/or nonprescription PPIs; (b) pharmacologic treatment with prescription-strength acid suppression therapy; (c) surgery; and d) endoscopic therapies (Table 50-2).[1,29] The initial therapeutic modality used is in part dependent on the patient's condition (frequency of symptoms, degree of esophagitis, and presence of complications) (Table 50-3). A step-down approach, starting with a PPI, instead of an H2RA, is most often advocated. Once esophageal healing has occurred or symptoms improved, patients should be stepped down to the lowest effective dose of PPI or switched to an H2RA. The clinician should determine the most appropriate approach for the individual patient. Every attempt should be made to aggressively control symptoms and to prevent relapses early in the course of the patient's disease in order to prevent the complications. For patients with moderate-to-severe GERD, especially those with erosive disease, starting with a PPI as initial therapy is advocated because of its superior efficacy over H2RAs.

TABLE 50-2

Evidence-Based Treatment Recommendations for GERD in Adults

Recommendation	Level of Evidence and Strength of Evidence[a]
Lifestyle Modifications	
• Weight loss in overweight GERD patients or those who have recently gained weight.	Moderate, Conditional
• Elevation of the head end of the bed and avoidance of food 2-3 hours before bedtime if nocturnal GERD symptoms present.	Low, Conditional
• Routine elimination of foods that can trigger reflux is not recommended in the treatment of GERD.	Low, Conditional
Acid Suppression Therapy	
• Therapy of choice for symptom relief and healing of erosive esophagitis is an 8-week PPI course. There is similar efficacy among all PPIs.	High, Strong
• For maximal pH control, delayed-release PPIs should be administered 30-60 minutes before meals.	Moderate, Strong
• PPIs should be started at once-daily dosing prior to the first meal each day.	Moderate, Strong

• Patients with Barrett's esophagus can be treated similarly to those with GERD who do not have Barrett's esophagus.	Moderate, Strong
• Flexibility with meal-time administration may be seen with newer PPIs (eg, dexlansoprazole).	Moderate, Conditional
• When clinically indicated, PPIs are considered safe in pregnancy.	Moderate, Conditional
• Adjustments of dose timing and/or twice-daily dosing may be beneficial in patients with night-time symptoms, variable schedules, and/or sleep disturbances who are partial responders to PPI therapy.	Low, Strong
• In patients with typical GERD symptoms who also have extraesophageal symptoms, a PPI trial is recommended.	Low, Strong
• Optimization of PPI therapy should be assessed in anyone with refractory GERD symptoms.	Low, Strong
• Increasing to twice-daily dosing or switching PPI may be beneficial in partial responders to PPI therapy.	Low, Conditional
• Further evaluation is recommended for nonresponders to PPI therapy.	Low, Conditional
• If adverse effects occur with PPI, may consider switching to an alternative PPI.	Low, Conditional
• Patients with osteoporosis can use a PPI.	Moderate, Conditional
• Concern for hip fracture with PPI should be considered in those with osteoporosis AND other risk factors for hip fracture.	Moderate, Conditional
• PPIs are a risk factor for development of *Clostridium difficile.*	Moderate, Moderate
• PPIs are a risk factor for development of community-acquired pneumonia with short-term use (but not long-term use).	Moderate, Conditional
• PPIs can be used in patients on clopidogrel, and there is not an increased risk for adverse cardiovascular events.	High, Strong
Promotility Therapy and Other Nonacid Suppression Therapies	
• Prokinetic medications and/or baclofen should not be used to manage GERD without diagnostic evaluation.	Moderate, Conditional
• Sulcralfate is not recommended in nonpregnant GERD patients.	Moderate, Conditional
Maintenance Therapy	
• Maintenance therapy is recommended for (1) patients with continued symptoms after PPI discontinuation and (2) patients with complications including erosive esophagitis and Barrett's esophagus.	Moderate, Strong

- The lowest effective dose should be used when long-term PPI therapy is indicated for maintenance. Strategies such as on-demand and intermittent therapy may be beneficial.	Low, Conditional
- H2RAs may be used as maintenance therapy in patients without erosive disease when the goal is heartburn relief.	Moderate, Conditional
Surgery	
- Antireflux surgery is a long-term treatment option in GERD patients.	High, Strong
- Antireflux surgery is not recommended in PPI nonresponders.	High, Strong
- Antireflux surgery is not recommended in patients with extraesophageal symptoms not responding to PPI therapy.	Moderate, Strong
- Endoscopic therapy or transoral incisionless fundoplication not recommended as alternative to medical or traditional surgical procedures.	Moderate, Strong
- Bariatric surgery (gastric bypass) should be considered in obese patients contemplating surgical therapy.	Moderate, Conditional

GERD, gastroesophageal reflux disease; PPI, proton pump inhibitor.

[a] Level of evidence per Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) system: High = further research not likely to change authors' confidence in the estimate of effect; Moderate = further research would likely have an impact on the confidence in the estimate of effect; Low = further research would be expected to have an important impact on the confidence in the estimate of the effect and would be likely to change the evidence. Strength of evidence per GRADE system: Strong = desired effects of an intervention clearly outweigh the undesirable effects; Conditional = there is uncertainty about the trade-offs between desirable effects and undesirable effects.

Data from References 1,29.

TABLE 50-3

Therapeutic Approach to GERD in Adults

Recommended Treatment Regimen	**Oral Dose**	**Comments**
Intermittent, mild heartburn (individualized lifestyle modifications + patient-directed therapy with antacids and/or nonprescription H$_2$RAs *or* nonprescription PPIs)		
Individualized lifestyle modifications		Lifestyle modifications should be individualized for each patient.
Patient-directed therapy with antacids (12 years of age or older)		
Magnesium hydroxide/aluminum hydroxide with	10-20 mL as needed or after meals and at	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention; do not exceed 16 teaspoonfuls per 24 hours.

simethicone	bedtime	
Antacid/alginic acid	2-4 tablets or 10-20 mL after meals and at bedtime	Note: Content of alginic acid varies greatly among products; the higher the alginic acid the better (at least 500 mg).
Calcium carbonate	500 mg, 2-4 tablets as needed	
Patient-directed therapy with nonprescription H2RAs (up to twice daily) (12 years of age or older)		
Cimetidine	200 mg	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention.
Famotidine	10-20 mg	
Nizatidine	75 mg	
Patient-directed therapy (over 18 years old) with nonprescription PPIs (taken once daily)		
Esomeprazole	20 mg	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention.
Lansoprazole	15 mg	
Omeprazole	20 mg	
Omeprazole/sodium bicarbonate	20 mg/1,100 mg	
Symptomatic relief of GERD (individualized lifestyle modifications + prescription-strength H2RAs *or* prescription-strength PPIs)		
Individualized lifestyle modifications		Lifestyle modifications should be individualized for each patient.
Prescription-strength H2RAs		
Cimetidine (off-label use)	400 mg four times daily or 800 mg twice daily	• For typical symptoms, treat empirically with prescription-strength acid suppression therapy. • If symptoms recur, consider maintenance therapy. Note: Most patients will require standard doses for maintenance therapy.
Famotidine	20 mg twice daily	
Nizatidine	150 mg twice daily	
Prescription-strength PPIs		
Dexlansoprazole	30 mg once daily for 4 weeks	• For typical symptoms, treat empirically with prescription-strength acid suppression therapy. • Patients with moderate-to-severe symptoms should receive a PPI as initial therapy. • If symptoms recur, consider maintenance therapy.
Esomeprazole	20-40 mg once daily	
Lansoprazole	15 mg once daily	

Omeprazole	20 mg once daily	
Omeprazole/sodium bicarbonate	20 mg once daily	
Pantoprazole (Off-label use)	40 mg once daily	
Rabeprazole	20 mg once daily	
Healing of erosive esophagitis or treatment of patients with moderate-to-severe symptoms or complications (individualized lifestyle modifications + high-dose H2RAs *or* PPIs *or* antireflux surgery)		
Individualized lifestyle modifications		Lifestyle modifications should be individualized for each patient.
PPIs (up to twice daily for up to 8 weeks)		
Dexlansoprazole	60 mg daily	• For extraesophageal or alarm symptoms, obtain endoscopy with biopsy to evaluate mucosa. • If symptoms are relieved, consider maintenance therapy. PPIs are the most effective maintenance therapy for patients with extraesophageal symptoms, complications, and erosive disease. Start with twice-daily PPI therapy if reflux chest syndrome present. • Patients not responding to pharmacologic therapy, including those with persistent extraesophageal symptoms, should be evaluated via manometry and/or ambulatory reflux monitoring.
Esomeprazole	20-40 mg daily	
Lansoprazole	30 mg once or twice daily	
Omeprazole	20 mg once or twice daily	
Rabeprazole	20 mg once or twice daily	
Pantoprazole	40 mg once or twice daily	
High-dose H2RAs (for 8-12 weeks)		
Cimetidine	400 mg four times daily or 800 mg twice daily	Note: If high-dose H_2RA needed, may consider using PPI to lower cost, increase convenience, and increase tolerability. Note: Four times daily H_2RA is considered off-label use for nizatidine.
Famotidine	20-40 mg twice daily	
Nizatidine	150 mg two to four times daily	
Interventional therapy		
Antireflux surgery Bariatric surgery Endoscopic therapies		

While weight loss in obese patients and elevation of the head end of the bed are beneficial for most GERD patients, recommending all lifestyle modifications to all patients is not recommended.[1] Instead, education on lifestyle modifications should be tailored to the individual needs of the patient. Table 50-4 lists some of the lifestyle modifications that can be recommended on an individualized basis.

TABLE 50-4

Nonpharmacologic Treatment of GERD with Lifestyle Modifications

- Elevate the head end of the bed (increases esophageal clearance). Use 6- to 8-inch (15-20 cm) blocks under the head side of the bed.
- Weight reduction (reduces symptoms) in obese patients.
- Avoid foods that may decrease lower esophageal sphincter pressure or increase transient lower esophageal sphincter relaxation (fats, chocolate, alcohol, peppermint, and spearmint).
- Include protein-rich meals in diet (augments lower esophageal sphincter pressure).
- Avoid foods that have a direct irritant effect on the esophageal mucosa (spicy foods, orange juice, tomato juice, and coffee).
- Behaviors that may reduce esophageal acid exposure.
- Eat small meals and avoid sleeping immediately after meals (sleep after 3 hours if possible; decreases gastric volume).
- Stop smoking (decreases spontaneous esophageal sphincter relaxation).
- Avoid alcohol (increases amplitude of the lower esophageal sphincter, peristaltic waves, and frequency of contraction).
- Avoid tight-fitting clothes.
- Always take drugs in the sitting upright or standing position and with plenty of liquid, especially for those that have a direct irritant effect on the esophageal mucosa (eg, bisphosphonates, tetracyclines, quinidine, potassium chloride, iron salts, aspirin, nonsteroidal anti-inflammatory drugs).

Data from Reference 20.

⑥ Patients with typical GERD symptoms should be treated with lifestyle modifications as appropriate and a trial of empiric acid suppression therapy. Those who do not respond to empiric therapy or who present with alarm symptoms such as dysphagia, weight loss, or GI bleeding should undergo endoscopy. Acid suppression therapy with PPIs or H2RAs is the mainstay of GERD treatment. Patients presenting with moderate-to-severe symptoms (with or without esophageal erosions) should be started on a PPI as initial therapy because it provides the most rapid symptomatic relief and healing in the highest percentage of patients.[1] H2RAs in divided doses are effective for patients with milder GERD symptoms. However, when standard doses of H2RA therapy are not effective at relieving symptoms, it is more cost effective and efficacious to switch to a PPI.

Promotility agents (such as metoclopramide) are not as effective as acid suppression agents. Combining a promotility agent with acid suppression medications offer only modest improvements in symptoms over standard doses of H2RAs and should not be routinely recommended. In addition, the availability of a promotility agent that has an acceptable adverse effect profile is lacking. Mucosal protectants, such as sucralfate, have a limited role in the treatment of GERD.

Maintenance therapy may be necessary to control symptoms and to prevent complications. For patients with more severe symptoms (with or without esophageal erosions) or for patients with other complications, maintenance therapy with a PPI is most effective. Routine use of combination therapy is not recommended in GERD maintenance therapy. In cases of refractory GERD, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose acid suppression therapy is considered.[1]

Nonpharmacologic Therapy

Nonpharmacologic treatment of GERD includes lifestyle modifications, antireflux surgery, bariatric surgery (in obese patients), and endoscopic therapies.

Lifestyle Modifications

The most common lifestyle modifications for GERD include weight loss in obese patients and elevation of the head end of the bed, especially for those patients who have symptoms while in a recumbent position.[1] Other lifestyle modifications should be individualized based on the patient's specific situation. These include consumption of smaller meals and not sleeping for at least 3 hours after eating, avoidance of foods or medications that exacerbate GERD, smoking cessation, avoidance of tight-fitting clothes, and avoidance of alcohol (see Table 50-4).[30]

Obesity increases the risk of GERD symptoms and complications including Barrett's esophagus. There is a clear association between BMI, waist circumference, and weight gain.[1] Surprisingly, weight gain in those considered to have a normal BMI is also associated with new onset GERD symptoms.[1] Even more alarming is the potential association between BMI and cancer in the esophagus and gastric cardia.[1] A high-fat meal will decrease LES pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal will elevate LES pressure. A weight loss goal of at least 10% is recommended to help to improve GERD symptoms.[30]

Elevating the head end of the bed by approximately 6 to 8 inches (15-20 cm) with a foam wedge under the mattress (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended. In general, anything that improves sleep hygiene may reduce GERD symptoms because TLESRs are reduced during sleep.[31] Many foods have been linked to worsening GERD symptoms; however, the evidence is weak for this association. Some foods decrease LES pressure (eg, fats and chocolates), while other foods can act as direct contact irritants to the esophageal mucosa (citrus juice, tomato juice, coffee, and pepper) (see Table 50-1).

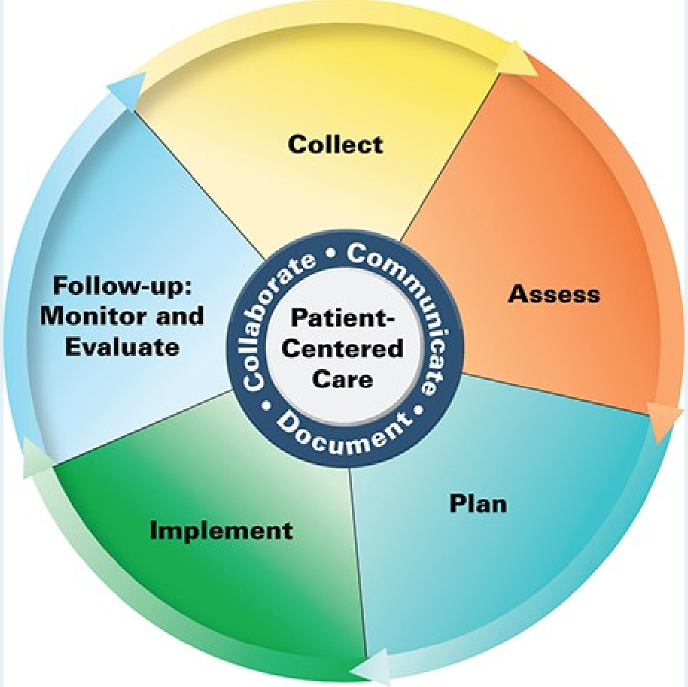
Evaluate patient profiles to identify potential medications that may exacerbate GERD symptoms (see Table 50-1). Some medications decrease LES pressure, while other medications can act as direct contact irritants to the esophageal mucosa. Proper patient education can help prevent dysphagia or esophageal ulceration. Closely monitor patients for worsening symptoms when any of these medications are started. If symptoms worsen, alternative therapies may be warranted. Clinicians must weigh the risks and benefits of continuing a medication known to worsen GERD and esophagitis.

Smoking can cause aerophagia (eg, air swallowing), which leads to increased belching and regurgitation. Patients with GERD should be encouraged to quit smoking because it may be a risk factor for Barrett's esophagus and esophageal adenocarcinoma.[21] Alcohol decreases LES pressure and may exacerbate symptoms such as heartburn.

Many patients are noncompliant with lifestyle modifications, and even those who do comply continue to have symptoms that require acid suppression therapy. Nonetheless, it is important to stress the potential benefits of lifestyle modifications that would benefit each individual patient.

PATIENT CARE PROCESS

Patient Care Process for the Management of Gastroesophageal Reflux Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, weight, BMI, pregnant)
- Patient history (past medical, family, social, dietary habits, tobacco use)
- Health literacy and barriers to medication access
- Thorough history of prescription, nonprescription, and natural medication use
- Medication allergies and intolerances (including actual reaction to medication)
- Laboratory results for major organ function (eg, SCr to calculate CrCL, liver enzymes to assess hepatic function)

Assess

- Assess major organ function (eg, creatinine clearance, hepatic impairment)
- Determine the type, frequency, duration of symptoms, and identify exacerbating factors
- Identify alarm symptoms or extraesophageal symptoms that require further diagnostic evaluation by clinician (see section “Clinical Presentation”)
- Review lifestyle factors, including foods that may be contributing to symptoms (see Table 50-1)
- Review medication profile for medications that may be contributing to symptoms (see Table 50-1) and potential drug–drug interactions
- Assess what has been done so far (including medications and lifestyle modifications)
- Establish goals of therapy and if they are currently being met (see section “Desired Outcomes”)
- Assess the appropriateness and effectiveness of current GERD regimen

Plan*

- Identify individualized lifestyle modifications that may improve symptoms (see Table 50-4)
- Determine appropriate therapy (may include both nonpharmacologic and pharmacologic) based on patient's presentation (see Table 50-2)
- For pharmacologic therapy, include medication name, dose, route, frequency, and duration of therapy recommendation (see Table 50-3)
- Establish monitoring parameters for safety (eg, drug–drug, drug–food, drug–disease, and drug–lab interaction checking; short- and long-term adverse effects, and prevention of complications)
- Establish monitoring parameters for efficacy (eg, resolution of symptoms, improvement of symptoms, and healing of injured mucosa) (see Table 50-5)
- Identify patient education that may be needed (eg, purpose of medication, individualized lifestyle modifications, adverse effects, administration clinical pearls, adherence, potential need for long-term maintenance therapy, and so on)
- For refractory symptoms, seek potential causes such as medication adherence, timing of medication, drug interactions, nonacid related disorders, and so on
- Screen for symptoms that would require further diagnostic evaluation from clinician (eg, alarm symptoms, atypical symptoms, or complications)

Implement*

- Counsel patient on individualized lifestyle modifications that may improve symptoms (eg, elevating head of the bed with a wedge, weight management, and so on) (see Table 50-4)
- Initiate appropriate nonpharmacologic and pharmacologic therapy based on patient presentation (see Tables 50-2 and 50-3)
- Recommend additions, modifications, or discontinuations to therapy based on patient response
- Provide patient education with regard to disease state, lifestyle modifications, and treatment plan. Counsel patient on (a) what causes GERD and things to avoid; (b) when to take their medication (eg, 30 minutes before meal); (c) what potential adverse effects (including long-term adverse effects) or drug interactions may occur
- Use motivational interviewing techniques to maximize medication adherence
- Schedule follow-up as appropriate

Follow-Up: Monitor and Evaluate

- Follow-up after 8 to 16 weeks to assess effectiveness of acid-suppression therapy. Recommend alternative therapy when necessary; attempt to deprescribe PPIs if possible
- Monitor patient for safety goals established above
- Evaluate the need for maintenance therapy based on patient presentation and response to therapy
- Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being
- Evaluate patient for the presence of adverse drug reactions, complications or new drug–drug interactions
- Stress the importance of medication adherence to treatment plan to patient as indicated

**Collaborate with patient, caregivers, and other healthcare professionals.*

Interventional Approaches

Interventional approaches include antireflux surgery, bariatric surgery, magnetic sphincter augmentation, and endoscopic therapies. These are discussed in more detail below.

Antireflux Surgery

⑦ The goal of antireflux surgery is to reestablish the antireflux barrier, to position the LES within the abdomen where it is under positive (intra-abdominal) pressure, and to close any associated defect in the diaphragmatic hiatus by reinforcing the crural muscles. Surgical intervention is a viable alternative treatment for select patients. It is indicated when (1) long-term pharmacologic management is undesirable, (2) persistent proven GERD symptoms or esophageal mucosal damage despite appropriate pharmacologic therapy, and (3) significant EGJ disruption (eg, hiatal hernia).[22] Antireflux surgery does not impact the progression of Barrett's esophagus to esophageal adenocarcinoma.[13] The most common antireflux surgery performed is laparoscopic Nissen fundoplication. Patients should undergo ambulatory reflux pH monitoring and manometry prior to antireflux surgery.[31] Patients with typical symptoms who are responsive to PPIs and those with abnormal ambulatory pH monitoring showing positive correlation with GERD symptoms show the most benefit from antireflux surgery, while those with extraesophageal symptoms show a lower response to antireflux surgery. The major complications with antireflux surgery include gas bloat syndrome (inability to belch or vomit), dysphagia, vagal denervation, and splenic trauma. Long-term effectiveness of antireflux surgery is uncertain.[33]

Success of antireflux surgery in patients with PPI-refractory heartburn depends on careful screening and ruling out nonacid related causes of heartburn, such as eosinophilic esophagitis, achalasia, and biliary disease. Seventy-eight percent of the patients with "refractory GERD" evaluated did not have reflux-related disease. Instead, they had non-GERD esophageal disorders or functional heartburn. In those who were PPI-refractory and had reflux-related heartburn, surgery was superior to medical treatment (67% versus 12%-28%, respectively).[34]

Bariatric surgery, specifically laproscopic Roux-en-Y gastric bypass, should be considered in obese patients (BMI greater than 35 kg/m^2) contemplating surgery.[1] The consideration of bariatric surgery in obese patients for improvement of GERD symptoms is a result of the proposed difference in pathophysiology in this patient population. Abdominal pressure may play a greater role in the development of GERD in obese patients. Reflux symptoms were decreased from 31% to 5%, esophagitis was decreased from 24% to 10%, and incidence of GERD was decreased from 34% to 12% with laparoscopic Roux-en-Y gastric bypass surgery in morbidly obese patients.[13]

Magnetic Sphincter Augmentation

This minimally invasive alternative to antireflux surgery involves surgically implanting a ring of titanium-encased magnets at the EGJ to improve lower esophageal resistance and reduce symptoms of GERD.[24,35] Long-term effectiveness of magnetic sphincter augmentation is uncertain.

Endoscopic Therapies

Endoscopic therapies are less invasive than surgical fundoplication and aim for a similar efficacy. Two endoscopic therapies are radiofrequency ablation of the LES and endoscopic suturing of the LES (transoral incisionless fundoplication). Radiofrequency ablation is recommended in patients with Barrett's esophagus with esophageal high-grade dysplasia. Guidelines also acknowledge radiofrequency ablation as a treatment option in low-grade dysplasia.[21] Transoral incisionless fundoplication creates a valve at the EGJ and is beneficial in patients with chronic GERD with abnormal ambulatory pH monitoring or low-grade erosive esophagitis with either no hiatal hernia or a hiatal hernia less than or equal to 2 cm.[31] However, it was less effective than laparoscopic Nissen fundoplication.[36]

Pharmacologic Therapy

Pharmacologic treatment consists of (a) patient-directed therapy with nonprescription antacids, H2RAs, or PPIs and (b) prescription-strength acid suppression therapy, or (c) promotility medications. Because of clinical similarities to other GI disorders, such as functional heartburn, eosinophilic esophagitis, and reflux hypersensitivity, which are not acid-related disorders, "proven" GERD should be diagnosed prior to committing a patient to long-term acid suppression therapy. Considering alternative therapies may be more appropriate for these non-GERD indications that may be more affiliated with modulating effects of anxiety or visceral and central hypersensitivity.[3]

Patient-Directed Therapy

Patient-directed therapy, where patients self-treat themselves with nonprescription medications, is appropriate for mild, intermittent symptoms. Patients with continuous symptoms lasting longer than 2 weeks should seek medical attention.[4] Self-treatment without further evaluation should also be avoided when the duration of severe or nocturnal heartburn exceeds 3 months, patient is symptomatic while taking prescription strength acid suppression therapy, or in the presence of alarm symptoms.[4]

Antacids and Antacid–Alginic Acid Products

Patients should be educated that antacids are an appropriate component of treating milder GERD symptoms, even though documentation of their efficacy in placebo-controlled clinical trials is lacking. Antacids may offer immediate symptomatic relief and help maintain the intragastric pH greater than 4, which decreases the activation of pepsinogen to pepsin, a proteolytic enzyme. The neutralization of gastric fluid may also lead to increased LES pressure. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription strength acid suppression therapy.

Some antacid products are combined with alginic acid, which is not a potent neutralizing agent and does not enhance LES pressure; however, it does form a highly viscous solution or “raft” that floats on the surface of the gastric contents. This viscous solution serves as a protective barrier for the esophagus against reflux of gastric contents and reduces the frequency of the reflux episodes. The alginic acid “raft” can adapt to the acid pocket, continuously floating above newly secreted acid near the EGJ. The combination product may be superior to antacids alone in relieving the symptoms of GERD.[37] There was a significant benefit favoring alginate therapy when compared to antacids in GERD; however, with moderate heterogeneity.[37] Alginate may also improve symptoms in patients on once-daily PPI still having residual reflux symptoms.[38] Liquid containing sodium alginate 1,000 mg/20 mL was more effective than an antacid without sodium alginate in controlling esophageal acid exposure after meals.[39] Efficacy data indicating endoscopic healing are lacking. There are many products with varying amounts of alginic acid. Some of the products contain lower amounts of alginic acid or list alginic acid under inactive ingredients with no amounts specified. Products with a higher alginic acid component are preferred (eg, 500 mg or higher amount of alginc acid). Patients should be encouraged to check medication labels for ingredients.

Antacid or antacid combination products interact with a variety of medications by altering gastric pH, increasing urinary pH, adsorbing medications to their surfaces, providing a physical barrier to absorption, or forming insoluble complexes with other medications. Antacids have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, sulfonylureas, and quinolone antibiotics. Antacid–drug interactions are influenced by composition, dose, dosage schedule, and formulation of the antacid. They may also cause constipation or diarrhea depending on the magnesium or aluminum content.

Dosage recommendations for antacids in the management of GERD are somewhat difficult to derive from the literature. Doses range from hourly to an as-needed basis (see Table 50-3). In general, antacids have a short duration of action, which necessitates frequent administration throughout the day to provide continuous neutralization of acid. Taking antacids after meals can increase the duration of action from about 1 to 3 hours; however, nighttime acid suppression cannot be maintained with bedtime doses.

Nonprescription H2RAs and Proton Pump Inhibitors

Nonprescription H2RAs (cimetidine, famotidine, and nizatidine) are effective in diminishing gastric acid secretion when taken prior to meals and decrease GERD symptoms associated with exercise. Antacids may have a slightly faster onset of action, while the H2RAs have a much longer duration of action compared with antacids.

The PPIs esomeprazole, omeprazole (alone or combined with sodium bicarbonate), and lansoprazole are available without a prescription for the short-term treatment of heartburn.

Acid Suppression Therapy

⑧ Acid suppression is the mainstay of GERD treatment. PPIs provide the greatest symptom relief and the highest healing rates, especially for patients with erosive disease, moderate-to-severe symptoms, or complications.

Proton Pump Inhibitors

PPIs (dexlansoprazole, esomeprazole, lansoprazole, omeprazole [with or without sodium bicarbonate], pantoprazole, and rabeprazole) block gastric acid secretion by inhibiting gastric H^+/K^+-adenosine triphosphatase in gastric parietal cells. This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH greater than 4, even during postprandial acid surges. A correlation exists between the percentage of time the gastric pH remains greater than 4 during the 24-hour period and healing erosive esophagitis.

The efficacy in treating GERD is similar among all of the PPIs.[31] Symptomatic relief is seen in approximately 83% of patients with endoscopic evidence of injury after 8 weeks treated with a PPI, whereas the endoscopic healing rate at 8 weeks is 78%.[1] Symptom response to NERD is less robust with approximately 60% of patients experiencing complete relief with PPI therapy.[1] PPIs are superior to H2RAs in treating moderate-to-severe GERD and should be given empirically to those with troublesome symptoms. This includes not only patients with esophageal tissue injury (eg, Barrett's esophagus, strictures, or esophagitis) but also patients with symptom-based GERD syndromes. Patients with uncomplicated GERD who respond well to a short-term course of PPI therapy should attempt to discontinue or to lower to the lowest effective dose.[40,41] Rebound acid hypersecretion may occur when PPIs are withdrawn making deprescribing of PPIs difficult. While no specific deprescribing or tapering regimen is recognized, strategies could include tapering dose down over 4 to 6 weeks, on-demand dosing, or abrupt discontinuation. One approach is to lower the dose by going from twice daily to once daily or halving the dose; or stopping the PPI and using an on-demand-regimen.[42] Up to 30% of patients on long-term PPI therapy could discontinue use and up to 80% were able to lower the dose.[43] PPI on-demand dosing was just as effective as low dose maintenance therapy for GERD symptoms.[44,45] Abrupt discontinuation of PPI therapy, while not ideal due to increased risk of rebound GERD symptoms, could be a reasonable option in select patients.

Twice-daily PPI use is indicated in those not responding to a standard once-daily course of therapy. Before increasing the frequency to twice daily, optimization of PPI therapy should be assessed (eg, taken 30-60 minutes prior to largest meal each day). In patients who are partial responders to initial PPI therapy, a trial of an alternative PPI may also be considered. Either strategy (twice-daily PPI or switching to an alternative PPI) has resulted in about a 20% improvement in symptoms with neither strategy demonstrating a clear advantage.[1] Partial response may also be due to abnormal patient perception, altered motility, or impaired LES dynamics where adjunctive therapy addressing the underlying cause may be helpful.[46] Patients with Barrett's esophagus should be treated similar to patients without Barrett's esophagus.[1] Further diagnostic evaluation is indicated for patients not responding to twice-daily PPI therapy.

The most common adverse effects associated with PPIs include headache, diarrhea, nausea, and abdominal pain. Increasing concerns regarding PPI safety continue to be reported. Community-acquired pneumonia may occur with short-term use in GERD patients.[1] Enteric infections, vitamin B12 deficiency, hypomagnesemia, and bone fractures are potential long-term adverse effects associated with PPIs (Table 50-5).[28,40,47,48] Gastric acidity plays an important role in the absorption of minerals such as calcium and magnesium, as well as with vitamin B12. While PPIs do not have a direct effect on the pH in the colon, they do have a downstream effect on colonic bacteria increasing the risk for *Clostridioides difficile* infections.[40,48] There is no evidence to support the use of probiotics in patients on long-term PPIs to prevent infection.[40] Despite potential concerns, data are lacking to recommend calcium, vitamin B12, or magnesium intake above the recommended daily allowance, unless there are other risk factors that warrant additional supplementation. Likewise, routine screening or monitoring of bone mineral density, serum creatinine, magnesium, or vitamin B12 levels are not recommended just because the patient is on long-term PPI therapy.[40] Another concern is chronic kidney disease. Proposed mechanisms for kidney injury include repeated bouts of acute interstitial nephritis, concurrent NSAID use, diabetes, and hypomagnesemia. Chronic kidney disease occurred in 3.68% of patients started on a PPI over a 5-year period compared to 2.56% in patients on an H2RA (Hazard ratio [HR] = 1.28). No association between PPI use and myocardial infarction has been clearly demonstrated.[48]

TABLE 50-5

Drug Monitoring

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Antacids			

• Magnesium hydroxide/aluminum hydroxide • Antacid/alginic acid • Calcium carbonate	• Diarrhea or constipation (depending on product) • Alterations in mineral metabolism • Acid–base disturbances	• Periodic calcium and phosphate levels in patients on chronic therapy	• Use caution with aluminum- and calcium-containing antacids in patients with renal impairment • Aluminum-containing antacids may bind to phosphate in the gut and lead to bone demineralization
H2RAs			
• Cimetidine • Famotidine • Nizatidine	• Headache, somnolence, fatigue, dizziness, and either constipation or diarrhea	• Monitor for CNS effects, especially in older patients	• May see increased CNS effects (rare) in those over 50 years of age or in those with renal or hepatic dysfunction • May be associated with vitamin B_{12} deficiency with longer duration therapy and in higher doses
Proton Pump Inhibitors			
• Dexlansoprazole • Esomeprazole • Lansoprazole • Omeprazole • Omeprazole/sodium bicarbonate • Pantoprazole • Rabeprazole	*Most common adverse effects:* • Headache, dizziness, diarrhea, flatulence, abdominal pain, and nausea *Other important adverse effects:* • Enteric infections • Community-acquired pneumonia *Long-term adverse effects:* • Hypomagnesemia • Bone fractures • Vitamin B_{12} deficiency • Chronic kidney disease	• Number and type of diarrhea episodes • Periodic magnesium levels warranted in those on higher doses or who are on therapy for greater than 1 year • Routine bone density studies or calcium supplementation should only be considered if other risk factors for osteoporosis or bone fractures are present • Respiratory symptoms within first 30 days of therapy • Periodic (not routinely) vitamin B_{12} serum concentration with long-term use	• Acid suppression may result in loss of host defense against ingested spores and bacteria permitting a higher burden of exposure • Hypomagnesemia is uncommon but can be serious; more likely in those on PPIs greater than 1 year • May increase risk for osteoporosis-related fractures of the hip, wrist, or spine; most common with high-dose (eg, multiple daily doses) and long-term use (eg, more than 1 year) and patients with osteoporosis can remain on PPI • PPIs may inhibit secretion of intrinsic factor, which potentially can lead to vitamin B_{12} deficiency; this is not common and usually associated with use for greater than 3 years • May increase risk of community-acquired pneumonia, particularly within the first 30 days of therapy

Data from References 28,40,47,48.

An increased risk of PPI-induced hepatic encephalopathy has been suggested.[48] The mechanism of this toxicity is related to alterations in the gut microbiota. Hypochlorhydria may lead to small bowel bacterial overgrowth which may contribute to hepatic adverse events. The risk of dementia or cognitive decline in patients receiving PPIs has raised concerns in the lay press; however, the evidence for this association is weak.[40] Vitamin B12 deficiency and enhanced beta-amyloid levels are potential contributing factors related to the potential cognitive decline associated with PPI use.[48]

Most of this data on these long-term adverse events are from observational studies and results have been variable. The first and largest prospective, randomized trial that examined PPI safety for up to 3 years found no difference in most adverse outcomes previously associated with long-term PPI use.[49] The one outcome that occurred more often in the PPI group was non-*Clostridioides difficile* enteric infections. Based on the results of this trial, limiting use of PPIs due to concerns regarding long-term effects is not warrented.[49] Overuse of PPI should still be minimized until the clinical implications of chronic therapy are better elucidated as more patients remain on PPI therapy for more than 3 years. Best practice advice from the American Gastroenterology Association states there is no convincing evidence to rank PPI formulations on potential risks.[40] More importantly, changing the paradigm to a more individualized approach to diagnosing GERD has been advocated based on careful assessment of anatomy, motor function, reflux burden, and symptomatic phenotype as a strategy to reduce the overuse of PPIs.[22] Clinicians should strive to identify a clear indication for PPI use before long-term therapy is considered. Deprescribing PPIs to reduce the potential for long-term adverse effects is important. Proper patient education should be done to ensure that appropriate patients are selected for PPI dose reductions or discontinuations to avoid adverse outcomes.[50,51]

Drug interactions with the PPIs vary slightly with each agent. All PPIs can decrease the absorption of medications such as ketoconazole or itraconazole, which require an acidic environment to be absorbed. Concerns have been raised regarding the concomitant use of PPIs, particularly omeprazole, with clopidogrel since it is the strongest inhibitor of CYP2C19.[52] Clopidogrel, a prodrug, is converted to its active metabolite via the CYP2C19 and CYP3A4 enzymes. Inhibition of CYP2C19 by PPIs, specifically omeprazole, may possibly decrease the effectiveness of clopidogrel.

Another consideration, particularly with omeprazole, is the potential polymorphic gene variations seen in the hepatic activity of CYP2C19. This is especially true for patients who are considered “slow metabolizers” of omeprazole, which is not only more common in Asian patients but also found in approximately 3% of White patients. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers. Like omeprazole, the metabolism of esomeprazole may also be altered for patients with this polymorphic gene variation. Despite these concerns, there are certain patients with upper GI bleeding or those with multiple risk factors for GI bleeding who require antiplatelet therapy would benefit from PPI therapy. Risk factors for GI bleeding include advanced age, use of anticoagulants, steroids or NSAIDs, presence of *H. pylori*, or previous history of bleeding or peptic ulcer disease complications.[53] For patients on clopidogrel, using an alternative acid suppression agent, such as an H2RA, or a PPI other than omeprazole and esomeprazole or using an alternative antiplatelet agent may be an acceptable alternative if there are concerns.

The PPIs degrade in acidic environments and therefore are formulated in a delayed-release capsule or tablet formulation. Dexlansoprazole, esomeprazole, lansoprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. Dexlansoprazole is unique in that the capsule is a dual delayed-release formulation, with the first release occurring 1 to 2 hours after the dose and the second release occurring 4 to 5 hours after the dose. The clinical significance of this dual release is to allow the medication to have a longer lasting benefit, at least 16 to 18 hours. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets.

For patients who are unable to swallow the capsule or tablet, or for pediatric patients, there are several alternative administration methods available. The contents of the delayed-release capsules can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can be mixed in 8.4% sodium bicarbonate solution. Esomeprazole granules can be dispersed in water. Esomeprazole, omeprazole, and pantoprazole are also available in a delayed-release oral suspension powder packet, while lansoprazole is available as a delayed-release, orally disintegrating tablet. Esomeprazole and pantoprazole are available in an IV formulation, which offers an alternative route of administration for patients who are unable to take an oral PPI. Importantly, the IV product is not more efficacious than oral PPIs and is significantly more expensive. The IV product should not be routinely used in GERD.

Omeprazole is also available as a delayed-release tablet and in a combination product with sodium bicarbonate as an immediate-release capsule and oral suspension. This is the only immediate-release PPI, and it should be taken on an empty stomach at least 1 hour before a meal. Omeprazole powder for oral suspension offers an alternative to the delayed-release capsules, or IV formulation in adult patients with a nasogastric tube. The immediate-release capsule should be swallowed whole and not opened, sprinkled on food, or administered via nasogastric tube. The 20- and 40-mg immediate-release capsules have the same amount of sodium bicarbonate; therefore, two 20-mg capsules cannot be substituted for a 40-mg capsule.

Patients should be instructed to take their PPI in the morning, 30 to 60 minutes before breakfast or before their biggest meal of the day, to maximize efficacy. Dexlansoprazole can be taken without regard to meals. Patients with nocturnal symptoms may benefit from taking their PPI prior to the evening meal. If dosed twice daily, the second dose should be administered approximately 10 to 12 hours after the morning dose and prior to a meal or snack.

H2RAs

H2RAs (cimetidine, famotidine, and nizatidine) in divided doses are effective in treating patients with mild-to-moderate GERD.[1]

The efficacy of H2RAs in the management of GERD is extremely variable and is frequently lower than desired. Response to the H2RAs is dependent on the (a) severity of disease, (b) dosage regimen used, and (c) duration of therapy. These factors are important when comparing clinical trials and/or assessing a patient's response to therapy. The severity of esophagitis at baseline has a profound impact on the patient's response to H2RAs. For symptomatic relief of mild GERD, low-dose, nonprescription H2RAs or standard doses given twice daily may be beneficial. Patients who do not respond to standard doses may be hypersecreters of gastric acid and will require higher doses. Although higher doses of H2RAs may provide higher symptomatic and endoscopic healing rates, limited information exists regarding the safety of these regimens, and they can be less effective and more costly than once-daily PPIs. Unlike duodenal ulcer disease, in which the duration of therapy is relatively short (eg, 4-6 weeks), prolonged courses of H2RAs are frequently required in the treatment of GERD.

Because all of the H2RAs have similar efficacy, selection of the specific agent to use in the management of GERD should be based on factors such as differences in pharmacokinetics, safety profile, and cost. Patients should be monitored for the presence of adverse effects, as well as potential drug interactions, especially when taking cimetidine. Cimetidine may inhibit the metabolism of theophylline, warfarin, phenytoin, nifedipine, and propranolol, among others. An alternate H2RA should be selected if the patient is on any of these medications. Headache, fatigue, dizziness, and constipation/diarrhea are the most common adverse effects associated with the use of H2RAs. Tachyphylaxis commonly occurs with H2RAs rendering them ineffective after a period of time in some patients. Ranitidine was taken off the US market in 2020 due to contamination with N-nitrosodimethylamine. The age of the product and storage temperatures were noted to accelerate production of this contaminant linked to cancer.

Promotility Agents

Promotility agents may be useful as an adjunct to acid suppression therapy for patients with a known motility defect (eg, LES incompetence, decreased esophageal clearance, and delayed gastric emptying). Unfortunately, all available promotility agents are fraught with undesirable adverse effects and are not as effective as acid suppression therapy.

Metoclopramide

Metoclopramide, a dopamine antagonist, increases LES pressure in a dose-related manner and accelerates gastric emptying in gastroesophageal reflux patients. However, it does not improve esophageal clearance. Metoclopramide provides symptomatic improvement for some patients with GERD; however, substantial data supporting endoscopic healing are lacking. In addition, metoclopramide's adverse effect profile, including extrapyramidal effects, tardive dyskinesia, and other central nervous system (CNS) effects, limits its usefulness in treating many patients with GERD. The risk of adverse effects is much greater for older patients and for patients with renal dysfunction because the drug is primarily eliminated by the kidneys. Contraindications include Parkinson's disease, mechanical obstruction, concomitant use of other dopamine antagonists or anticholinergic agents, and pheochromocytoma.

Bethanechol

Bethanechol, a promotility drug, has limited value in the treatment of GERD because of unwanted adverse effects, such as urinary retention, abdominal discomfort, nausea, and flushing. It is not routinely recommended for the treatment of GERD.

Mucosal Protectants

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has limited value in the treatment of GERD. It may not be useful in the routine treatment of acid reflux but may be useful in the management of radiation esophagitis and bile or nonacid reflux GERD.

Combination Therapy

Combination therapy with an acid suppression agent and a promotility agent or a mucosal protectant agent would seem logical given the multifactorial nature of the disease, particularly in light of the disappointing results seen with many monotherapy regimens. However, data to support combination therapy are limited, and this approach should not routinely be recommended unless a patient has GERD plus motor dysfunction occurring. The effectiveness of the addition of an H2RA at bedtime to PPI therapy for the treatment of nocturnal symptoms may decrease over time due to tachyphylaxis with H2RAs. Therefore, “as needed” use of bedtime H2RA may be a more appropriate approach if combination with a PPI is deemed necessary. Using the omeprazole–sodium bicarbonate immediate-release product in addition to once-daily PPIs may offer an alternative for nocturnal GERD symptoms.

Maintenance Therapy

⑨ Many patients with GERD will relapse if medication is withdrawn; therefore, long-term maintenance treatment may be required. A PPI is the drug of choice for maintenance of patients with moderate-to-severe GERD, erosive disease, or other complications such as Barrett's esophagus. Patients who have symptomatic relapse following discontinuation of therapy or lowering of medication doses should be considered for long-term maintenance therapy to prevent complications or worsening of esophageal function.[1]

In patients with uncomplicated GERD who respond to short-term PPI therapy, lowering the PPI dose or discontinuing the PPI should be considered. If this is not possible, ambulatory reflux pH with or without impedance monitoring should be performed to assure symptoms are GERD-related prior to committing to lifelong PPI use.[40] Patients receiving chronic PPI therapy should be periodically evaluated to assure the lowest possible effective dose is used.[40,60] The goal of maintenance therapy is to improve quality of life by controlling the patient's symptoms and preventing complications. Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy in order to prevent recurrence or worsening of disease. H2RAs may be an effective maintenance therapy for patients with mild disease.[1] Low doses of a PPI or alternate-day dosing may be effective in some patients with mild symptoms, thereby allowing dose reduction in some cases. “On-demand” or intermittent maintenance therapy, by which patients take their PPI only when they have symptoms, may be effective for patients with endoscopy-negative GERD.[1,31] Many patients with only mild-to-moderate symptoms may decide on their own to use “on-demand” for the financial benefit and patient satisfaction.[31] However, patients with persistent symptoms and/or complications require standard doses of PPIs.

Studies evaluating the efficacy of the H2RAs in maintaining patients with GERD in remission have been disappointing. No currently available H2RA regimen is FDA approved for maintenance of healing of erosive esophagitis. Antireflux surgery may also be considered a viable alternative to long-term drug therapy for maintenance of healing for patients who are candidates.

Special Populations

There are several special populations that should be considered when discussing GERD, such as patients with extraesophageal symptoms, pediatric patients, older patients, and patients with refractory symptoms.

Patients with Extraesophageal GERD

Extraesophageal symptoms (such as asthma, laryngitis, or chest pain) should prompt investigation for other possible causes outside of GERD. Because there are many causes of asthma and laryngeal symptoms, a concomitant esophageal GERD syndrome must also be present to associate these symptoms with GERD. A trial of PPI therapy is recommended for those with extraesophageal symptoms with concurrent typical GERD symptoms. Patients with extraesophageal symptoms without typical GERD symptoms should undergo ambulatory reflux monitoring prior to initiation of PPI therapy. If symptoms continue, patients should be evaluated with manometry or ambulatory reflux monitoring with or without impedance to rule out dysmotility or refractory symptoms, respectively.[1] Ambulatory reflux montoring while on PPI is useful for those with “proven” GERD while testing while off PPI is useful when the goal is to identify moderate-to-severe reflux at baseline.[54]

In patients with chronic cough suspected to be reflux related, lifestyle modifications are recommended.[55] Acid suppression therapy is unlikely to be beneficial if heartburn or regurgitation is not also present. If the patient does have concomitant heartburn or regurgitation with a chronic cough, PPI therapy may be beneficial but may take up to 3 months before resolution of cough.[55] After 3 months, more diagnostic evaluation is needed.

Pediatric Patients with GERD

Many infants have physiologic reflux with little or no clinical consequence. Uncomplicated gastroesophageal reflux usually manifests as regurgitation or “spitting up” and resolves without incident by about 12 months of life.[16] When evaluating a child for GERD, conduct a history and physical examination. If alarm signs are present, clinicians should tailor testing to address the alarm signs and refer appropriately. If no alarm signs are present, lifestyle and dietary education should be initiated. Symptoms usually respond to supportive therapy, including dietary adjustments, postural management, and reassurance for the parents. Thickened feedings may be useful in milder cases. While this does not decrease reflux episodes, it may decrease the incidence of regurgitation.[16] This strategy of thickening feedings may be appropriate for full-term infants; however, may be associated with necrotizing enterocolitis in preterm infants. Chronic vomiting associated with gastroesophageal reflux must be distinguished from other causes, such as neurologic, metabolic, eating, and rumination disorders. Smaller, more frequent feedings may be beneficial. In formula-fed infants, an extensively hydrolyzed protein may help identify milk protein sensitivity as the cause of unexplained GERD-like symptoms, likewise, exclusion of milk and eggs in the maternal diet for breastfeeding infants may be appropriate.[16] Additionally, a trial of an amino acid based formula should occur prior to a trial of acid suppression therapy. If lifestyle and dietary education do not resolve the GERD symptoms, a 4- to 8-week trial of acid suppression therapy is recommended.[16] Once a 4- to 8-week course is complete, referral to a pediatric GI specialist is recommended if symptoms are not improved or recur upon weaning therapy.[16]

Developmental immaturity of the LES is one suspected cause of gastroesophageal reflux in infants. Like adults, TLESRs seem to be the most common cause of gastroesophageal reflux in children. Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula. Complications, although rare, include distal esophagitis, failure to thrive, esophageal peptic strictures, Barrett's esophagus, and pulmonary disease. Further diagnostic evaluation is indicated in all who experience apnea or an apparent life-threatening event.

The benefits of using promotility medications, such as metoclopramide, erythromycin, bethanechol, and baclofen, are outweighed by the potential adverse effects that may occur and, therefore, cannot be routinely recommended.[16] Careful consideration should be made before medication is recommended, especially in children younger than 1 year of age.

PPI use in children is increasing, especially in those with esophagitis. Most patients will respond to once-daily PPI dosing. In infants with reflux-related esophagitis, the use of PPIs is the first-line treatment option.[16] Table 50-6 details indications and dosing of PPIs in pediatric patients. Dexlansoprazole and pantoprazole have not been adequately studied in younger pediatric patients. When examining adverse effect data from currently available trial data the authors noted that overall PPI therapy was well tolerated with mostly mild-to-moderate adverse effects in the short term. Adverse effects with individual agents included diarrhea, abdominal pain, and vomiting with headache noted in older age groups and upper and lower respiratory tract infections noted in infants. Long-term use of a PPI without a clear diagnosis of GERD is not recommended.[16]

TABLE 50-6

Oral Proton Pump Inhibitor Therapy in Pediatric Patients

Drug	Indication	Age	Recommended Oral Dose (daily)	
Dexlansoprazole	Symptomatic GERD, erosive esophagitis	≥12 years ≥12 years		30 mg 60 mg
Esomeprazole	Erosive esophagitis	1 month–1 year	3-5 kg	2.5 mg
			>5-7.5 kg	5 mg
			>7.5	10 mg

		1-11 years	<20 kg	10 mg
			≥20 kg	10-20 mg
		≥12 year		20-40 mg
	Symptomatic GERD		< 20 kg	10 mg
			> 20 kg	20 mg
Lansoprazole	Symptomatic GERD	Infants >3 months		7.5 mg twice daily or 15 mg daily
		1-11 years	≤30 kg >30 kg	15 mg 30 mg
		≥12 year		15 mg
	Erosive esophagitis	Infants >3 months		7.5 mg twice daily or 15 mg daily
		1-11 years	≤30 kg >30 kg	15-30 mg
		≥12 year		30 mg
Omeprazole	GERD, erosive esophagitis, maintenance of healing of erosive esophagitis	≥1 year	5 to <10 kg	5 mg
			10 to <20 kg	10 mg
			≥20 kg	20 mg
Pantoprazole	Symptomatic GERD			1-2 mg/kg/day
	Erosive esophagitis	≥5 years	≥15 to <40 kg	20 mg
			≥40 kg	40 mg
Rabeprazole	Symptomatic GERD	1-11 years	<15 kg	5-10 mg
			≥15 kg	10 mg
		≥12 years		20 mg

*Note: Oomeprazole also has dosing for treatment of erosive esophagitis in infants 3 kg to < 5 kg of 2.5 mg daily. Otherwise, dosing is the same for children and adolescents for all GERD indications.

Duration of therapy depends on age and indication.

Data from Reference 56.

Older Patients with GERD

Many older patients have decreased host defense mechanisms, such as saliva production. In addition, they have more comorbidities, medications, and physiologic changes that put them at higher risk. Often these patients do not seek medical attention because they feel their symptoms are part of the normal aging process. They may also present with atypical symptoms such as chest pain, asthma, poor dentition, or jaw pain. Decreased GI motility is a common problem in older patients. Unfortunately, there are no good promotility agents available to these patients. Older patients are especially sensitive to the CNS effects of metoclopramide. They may also be sensitive to the CNS effects of H2RAs. PPIs appear to be the most useful treatment modality, because they have superior efficacy and are dosed once daily, which is beneficial in all patients, but is especially beneficial in the older population. Long-term risk of bone fractures may be of concern in this population. Patients at risk for bone fractures should be monitored appropriately.

Patients with Refractory GERD

What constitutes refractory GERD is not well defined. Prior to increasing the dose to twice daily, adherence and proper administration timing of PPI therapy should be optimized. Refractory GERD should be considered in patients who have not responded to a standard course of twice-daily PPI therapy over a 12-week period. The most likely causes associated with PPI-refractory GERD include: (1) abnormal acid reflux despite PPI therapy; (2) reflux hypersensitivity where physiologic (normal) reflux causes symptoms; (3) esophageal disorders other than GERD (eg, achalasia); (4) extraesophageal disorders (eg, lung disease or heart disease); and (5) functional heartburn.[57,58] In some situations, variations in drug metabolism in certain patients may contribute to refractory GERD. Switching to another PPI or increasing the dose to twice daily may be beneficial; however, the latter may reduce compliance.[31] Rabeprazole is least affected by CYP enzymes and improves acid suppression in patients considered to be slow metabolizers of CYP 2C19.[57] Reeducating patients regarding lifestyle modifications is recommended.[31] Manometry or ambulatory esophageal reflux monitoring is useful for patients who are not responding to therapy who have normal endoscopic findings.

Patients with Los Angeles Grade C or D esophagitis, peptic stricture, Barrett's esophagus or pathologic acid exposure seen on ambulatory reflux pH monitoring (while off PPI) indicate "proven" GERD. These patients should undergo ambulatory reflux pH-impedance monitoring while on PPI therapy to determine if they are truly PPI-refractory or if contents are nonacidic in nature.[57] PPI-refractory GERD is associated with esophageal exposure time greater than 6% on PPI.[57] AET represents the percentage of time the esophageal pH is less than 4 over the monitoring period. If AET is normal then consider other non-GERD causes such as functional heartburn or reflux hypersensitivity. Patients with hypersensitive esophagus or functional heartburn do not respond as well to acid suppression therapy.[2]

The majority of patients with refractory symptoms experience nocturnal acid breakthrough. Dexlansoprazole offers greater dosing flexibility since it does not need to be administered with food so may provide effective control of nocturnal symptoms.[59] Likewise, omeprazole-sodium bicarbonate immediate-release products can be given without regard to meals and may be useful in controlling nocturnal symptoms.[59]

Antireflux surgery, magnetic sphincter augmentation, and endoscopic therapies may have a role in refractory GERD, depending on the scenario. If ambulatory reflux monitoring tests are negative, the patient is unlikely to have GERD and PPI therapy should be discontinued and alternative diagnosis should be investigated.[1] Baclofen may be beneficial for patients with residual acid or weakly acidic reflux by decreasing TLESRs, although with potential adverse effects seen in some patients.[31] Functional heartburn or reflux hypersensitivity may be treated with tricyclic antidepressants, selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, or trazodone.[5,31] Eosinophilic esophagitis or dysmotility syndromes are causes of nonacid-related esophageal symptoms and require therapies other than a PPI.[31,60]

EVALUATION OF THERAPEUTIC OUTCOMES

The long-term benefits of treatment are difficult to assess because of the limited information known about the epidemiology and natural history of GERD. Consequently, successful outcomes are measured in terms of three separate end points: (a) relieving symptoms, (b) healing the injured mucosa, and (c) preventing complications.

⑩ The short-term goal of therapy is to relieve symptoms such as heartburn and regurgitation to the point at which they do not impair the patient's quality of life. Patients should be educated regarding specific lifestyle modifications that are applicable to their individual situation including weight loss and raising the head end of the bed. Patient medication profiles should be reviewed for medications that may aggravate GERD. Patients should be monitored for adverse drug reactions and potential drug interactions. Deprescribing PPIs or tapering to the lowest effective dose is a key strategy in preventing adverse effects. Table 50-5 reviews common adverse drug reactions and monitoring of medications used in GERD. The frequency and severity of symptoms should be monitored, and patients should be counseled on symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia. Patients should also be monitored for the presence of extraesophageal symptoms, such as laryngitis asthma or chest pain. These symptoms require further diagnostic evaluation. Long-term maintenance treatment is indicated for patients who have strictures as they commonly recur if reflux esophagitis is not treated.

The second goal is to heal the injured mucosa. Again, individualized lifestyle modifications and the importance of complying with the therapeutic regimen chosen to heal the mucosa should be stressed. Patients should be educated about the risk of relapse and the need for long-term maintenance therapy to prevent recurrence or complications.

The final, long-term goal of therapy is to decrease the risk of complications (esophagitis, strictures, Barrett's esophagus, and esophageal adenocarcinoma). A small subset of patients may continue to fail treatment despite therapy with high doses of H2RAs or a PPI. Patients should be monitored for the presence of continual pain, dysphagia, or odynophagia.

ABBREVIATIONS

AET	acid exposure time
BMI	body mass index
EGJ	esophagogastric junction
GERD	gastroesophageal reflux disease
GI	gastrointestinal
HR	hazard ratio
H2RA	histamine-2 receptor antagonist
LES	lower esophageal sphincter
NERD	nonerosive reflux disease
NSAID	nonsteroidal anti-inflammatory drug
PPI	proton pump inhibitor
TLESR	transient lower esophageal sphincter relaxation
UES	upper esophageal sphincter

SELF-ASSESSMENT QUESTIONS

1. Which of the following represents an alarm GERD symptom?

   A. Regurgitation

   B. Chronic cough

   C. Dysphagia

   D. Heartburn

2. A 52-year-old male patient presents to his primary care physician and reports bothersome heartburn symptoms for the last 4 months with occasional regurgitation. The patient reports that the heartburn symptoms are occurring most days of the week. The patient also reports that he has developed painful, difficult swallowing over the last several months. What is the most appropriate recommendation for management of the patient's heartburn symptoms?

   A. Start omeprazole 20 mg daily and recommend antireflux surgery.

   B. Start omeprazole 20 mg daily and recommend endoscopy.

   C. Encourage lifestyle modifications and recommend ambulatory reflux monitoring.

   D. Start omeprazole 20 mg twice daily and recommend manometry.

3. A 42-year-old male patient with typical GERD symptoms occurring 4-5 days per week has been recently initiated on once-daily PPI therapy. The patient reports that his heartburn symptoms are most prominent overnight. The patient has no other medical history, and his BMI is 22 kg/m^2. As per the American College of Gastroenterology guidelines which of the following represents the best lifestyle modification to recommend for this

patient?

A. Elimination of all potential trigger foods in his diet

B. Reduce protein content in diet

C. Calorie restriction to lose 10% of his body weight

D. Elevation of the head of the bed (not with pillows)

4. A 38-year-old women experiencing frequent typical GERD symptoms was initiated on omeprazole once daily. The patient is reporting that her symptoms are less frequent and milder since initiating PPI therapy, but her symptoms remain bothersome. Which of the following is the best recommendation?

A. Change to ranitidine 150 mg twice daily.

B. Refer the patient for ambulatory reflux monitoring.

C. Initiate antacid as needed for breakthrough symptoms.

D. Change to pantoprazole 40 mg daily.

5. Tachyphylaxis is a limitation to maintenance therapy with which of the following?

A. Cimetidine

B. Dexlansoprazole

C. Calcium carbonate

D. Metoclopramide

6. Which of the following PPIs utilizes an immediate-release formulation?

A. Dexlansoprazole

B. Omeprazole/Sodium bicarbonate

C. Lansoprazole

D. Pantoprazole

7. Which of the following drugs is considered a risk factor for the development of bone fractures?

A. Metoclopramide

B. Famotidine

C. Rabeprazole

D. Alginic acid

8. Endoscopic evaluation is indicated in which of the following patients?

A. 47-year-old with a 10-year history of typical GERD symptoms well controlled on current proton pump inhibitor

B. 38-year-old with persistent heartburn after 2-week trial of over-the-counter famotidine 20 mg BID

C. 40-year-old with persistent typical GERD symptoms on pantoprazole 40 mg BID

D. 52-year-old with recurrence of symptoms after trial off of esomeprazole 20 mg daily

9. When attempting to discontinue/deprescribe PPI therapy, which of the following is an appropriate recommendation?

A. Adding an H2RA when the PPI is discontinued

B. Changing to an immediate-release PPI formulation

C. Overlapping an H2RA with PPI therapy before discontinuation

D. Tapering down the dose to the lowest dose that controls symptoms

10. Which therapy has been shown superior in patients with PPI-refractory heartburn?

A. Antireflux surgery

B. Radiofrequency ablation

C. Metoclopramide 10 mg four times daily

D. Famotidine 10 mg twice daily

11. The preferred initial treatment option for a 45-year-old male presenting with a 1-week history of GERD symptoms is:

A. Patient-directed therapy with nonprescription omeprazole

B. Prescription strength PPI

C. Antireflux surgery

D. Endoscopic therapy

12. Which of the following regimens would be most appropriate to prevent osteoporosis in a 25-year-old marathon runner on esomeprazole 20 mg daily for typical GERD symptoms?

A. Calciumcarbonate 1,250 mg three times daily

B. Calcium citrate 500 mg once daily

C. Elemental calcium 1.5 grams plus vitamin D 400 units once daily

D. No calcium indicated since he/she does not have risk factors for osteoporosis

13. Which of the following is a potential adverse effect of long-term PPI therapy?

A. Hypercalcemia

B. *Clostridium difficile* infection

C. Vitamin A deficiency

D. Hypokalemia

14. Which of the following patients would be most appropriate for a trial of patient-directed over-the-counter PPI therapy?

A. 37-year-old with 1-year history of dysphagia and odynophagia

B. 61-year-old with a 5-day history of heartburn and belching

C. 22-year-old with asthma and chronic cough

D. 44-year-old with a 3-month history of daily heartburn and regurgitation

15. Which of the following patients is the best candidate for maintenance therapy for GERD?

A. 37-year-old patient who relapses after an 8-week course of PPI therapy

B. 31-year-old patient with intermittent GERD symptoms

C. 52-year-old patient with scleroderma

D. 2-month-old baby with intermittent regurgitation of feeds

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Examples of alarm GERD symptoms include unexplained weight loss, dysphagia, odynophagia, or bleeding. See section "Clinical Presentation" for a complete discussion on the types of GERD symptoms.

2. **B.** Endoscopy is indicated in patients who present with alarm symptoms such as weight loss, dysphagia, odynophagia, or bleeding. See section "Clinical Presentation" (Diagnostic Tests) section of the chapter for additional information. A standard course of PPI therapy is also warranted.

3. **D.** The American College of Gastroenterology guidelines recommend elevation of the head of the bed and avoidance of meals 2-3 hours before bedtime in patients with nocturnal GERD. Weight loss is recommended in those that are overweight, which this patient is not. Routine global elimination of trigger foods is not recommended, and protein intake should be increased to improve reduced LES pressure. See section "Treatment" (Nonpharmacologic Therapy [Lifestyle Modifications]) of the chapter for more information.

4. **D.** The American College of Gastroenterology guidelines note that in patients with a partial response to PPI therapy that additional benefit may be seen by increasing the PPI to twice daily or trialing an alternative PPI. See section "Treatment" (Pharmacologic Therapy [Acid Suppression Therapy (PPI)]) of the chapter for more information.

5. **A.** Tachyphylaxis can occur with consistent administration of H2RAs. See section "Treatment" (Pharmacologic Therapy [Combination Therapy]) and (Pharmacologic Therapy [Special Populations (Patients with Refractory GERD)]) of the chapter for more information.

6. **B.** Omeprazole/Sodium bicarbonate is the only PPI available in an immediate-release formulation and it should be taken on an empty stomach at least one hour before a meal.

7. **C.** Proton pump inhibitors have been identified as a risk factor for the development of osteoporosis. See Table -5 Drug Monitoring section in the chapter for more information on monitoring parameters for acid suppressive therapies.

8. **C.** Endoscopy is used to assess for mucosal injury from GERD and to assess for other complications. It should be performed in patients with persistent or progressive GERD symptoms despite appropriate medical therapy. See section "Clinical Presentation" (Diagnostic Tests) of the chapter for more information

9. **D.** There are three strategies that have been studied and deemed reasonable when discontinuing/deprescribing PPI therapy; tapering down the dose, on-demand dosing, and abrupt discontinuation. "Treatment" (Pharmacologic Therapy [Acid Suppression Therapy (PPI)]) of the chapter for more information.

10. **A.** A recent VA study showed that laparoscopic Nissen fundoplication surgery (antireflux surgery) was shown to be superior to continuing PPIs in patients who were properly screened to rule out nonacid related causes of heartburn. More than two thirds of patients showed more than a 50% improvement in symptoms as one year compared to 28% with continued PPI use ($p = 0.007$). See section "Treatment" (Nonpharmacologic Therapy [Interventional Approaches (Antireflux Surgery)]) in chapter for more information.

11. **A.** Patientswith mild, intermittent GERD symptomsless thantwoweeks,are candidates for patient-directed therapy with a non-prescription medication (antacids, H2-receptor antagonist, or proton pump inhibitors). If symptoms do not resolve after the initial treatment period of about 2 weeks, further evaluation is warranted. See section “Treatment” (Pharmacologic Therapy [Patient-Directed Therapy] [Acid Suppression Therapy]) for more information.

12. **D.** Patients with no additional risk factors for osteoporosis should not receive additional calcium supplementation or screening or monitoring of bone mineral density because data is lacking to support these practices. See section “Treatment” (Pharmacologic Therapy [Acid Suppression Therapy (PPI)]) of the chapter for more information.

13. **B.** Gastric acidity plays an important role in the absorption of minerals such as calcium and magnesium, thus leading to low serum concentrations, as well as with vitamin B12 absorption. The change in pH also has a downstream effect on colonic bacteria increasing the risk for *Clostridium difficile* infections. PPIs have not been shown to have a significant effect on potassium homeostasis or Vitamin A absorption. See section “Treatment” (Pharmacologic Therapy [Acid Suppression Therapy (PPI)] of the chapter for more information.

14. **B.** Patient-directed therapy is appropriate when the patient’s symptoms are mild and intermittent. Patients with persistent symptoms, more severe symptoms (especially alarm symptoms such as dysphagia, or atypical symptoms (e.g., cough, asthma) will require a standard course of prescription strength acid suppression with a proton pump inhibitor. See section “Treatment” (Pharmacologic Therapy [Patient-Directed Therapy] [Acid Suppression Therapy (PPI)]) of the chapter for more information.

15. **A.** Maintenance therapy is indicated in patients who have symptomatic relapse following discontinuation of acid suppression therapy, especially those with more severe disease. It is also indicated for patients with complications such as Barrett’s esophagus or erosive esophagitis. See section “Treatment” (Pharmacologic Therapy [Maintenance Therapy]) of the chapter for more information.

Chapter 51: Peptic Ulcer Disease and Related Disorders

Bryan L. Love

KEY CONCEPTS

KEY CONCEPTS

①Psychological stress, cigarette smoking, nonsteroidal anti-inflammatory drug (NSAID) use, and certain foods/beverages can exacerbate ulcer symptoms and should be avoided.

②Eradication of *Helicobacter pylori* (*H. pylori*) is recommended for all patients who test positive, especially in those patients with an active ulcer, a documented history of a prior ulcer, or a history of ulcer-related complications.

③The selection of an *H. pylori* eradication regimen should be based on several factors, including efficacy, safety, antibiotic resistance, cost, and the likelihood of medication adherence. The recommended initial treatment options with the strongest level of evidence include bismuth quadruple and concomitant therapy, both administered for 10 to 14 days. Empiric clarithromycin-based triple therapy is no longer recommended due to increasing resistance and reduced eradication rates.

④When first-line therapy fails, salvage treatment for *H. pylori* should contain different antibiotics due to potential resistance. Patients with reported penicillin allergy should be considered for penicillin skin testing after failing first-line therapy since many can safely be treated with amoxicillin containing salvage regimens.

⑤PPI co-therapy reduces the risk of NSAID-related gastric and duodenal ulcers and is at least as effective as misoprostol and superior to histamine-2 receptor antagonists (H2RAs).

⑥Standard PPI dosages and a nonselective NSAID are as effective as a selective cyclooxygenase-2 (COX-2) inhibitor in reducing the risk of NSAID-induced ulcers and upper gastrointestinal (GI) complications.

⑦Patients with peptic ulcer disease (PUD), especially those receiving *H. pylori* eradication or misoprostol co-therapy, require patient education regarding their disease and drug treatment to successfully achieve a positive therapeutic outcome.

⑧Treatment for severe peptic ulcer bleeding after appropriate endoscopic treatment includes administration of a PPI either orally or parenterally via intermittent or continuous infusion targeting cumulative daily doses of 80 to 160 mg.

⑨Coagulopathy and respiratory failure requiring mechanical ventilation are the most notable risk factors for developing stress-related mucosal bleeding (SRMB). Prophylactic drug therapy should be administered to critically ill patients with either of these risk factors.

⑩Selection of a PPI over an IV H2RA for SRMB prophylaxis should be based on individual patient characteristics (eg, nothing by mouth, presence of nasogastric tube, thrombocytopenia, renal failure).

BEYOND THE BOOK

BEYOND THE BOOK

Create a table with two columns, one titled PPI and one titled H2RA. Create rows for Prevention of NSAID-induced ulcer disease and Stress Ulcer Prophylaxis. In each new cell, list advantages and disadvantages of using each medication class for these conditions. The purpose of this exercise is to familiarize students with the relative safety and efficacy for medications commonly used to treat PUD.

PEPTIC ULCER DISEASE

Gastric acid is a critical component of upper gastrointestinal (GI) tract complications including gastritis, erosions, and peptic ulcer.[2-4] Peptic ulcer disease (PUD) differs from gastritis and erosions in that ulcers are larger (greater than or equal to 5 mm) and extend deeper into the muscularis mucosa. The three common forms of peptic ulcers can be grouped according to their etiology: *Helicobacter pylori*–positive, NSAID–induced, and stress-related mucosal damage (SRMD) (Table 51-1).

TABLE 51-1

Comparison of Common Forms of Peptic Ulcer

Characteristic	*H. pylori*–Induced	NSAID-Induced	SRMD
Condition	Chronic	Chronic	Acute
Site of damage	Duodenum > stomach	Stomach > duodenum	Stomach > duodenum
Intragastric pH	More dependent	Less dependent	Less dependent
Symptoms	Usually epigastric pain	Often asymptomatic	Asymptomatic
Ulcer depth	Superficial	Deep	Most superficial
GI bleeding	Less severe, single vessel	More severe, single vessel	More severe, superficial mucosal capillaries

GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; SRMD, stress-related mucosal damage.

H. pylori–positive and NSAID-induced ulcers are chronic peptic ulcers that differ in etiology, clinical presentation, and tendency to recur (see Table 51-1). These ulcers develop most often in the stomach and duodenum of ambulatory patients (Fig. 51-1). Occasionally, ulcers develop in the esophagus, jejunum, ileum, or colon. The natural course of chronic PUD is characterized by frequent ulcer recurrence. The cause of ulcer recurrence is often multifactorial, although *H. pylori* infection and NSAID use are commonly associated. In addition, cigarette smoking, alcohol use, gastric acid hypersecretion, and medication nonadherence are frequently related.

FIGURE 51-1

Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers.

Conditions such as Zollinger-Ellison syndrome (ZES), radiation, chemotherapy, vascular insufficiency, and other chronic diseases (Table 51-2) are associated with development and recurrence of peptic ulcers.[2,3] Ulcer development at the gastro-jejunal anastomosis, termed marginal ulcers, occurs in patients with history of Roux-en-Y gastric bypass surgery and shares risk factors with PUD; however, the pathogenesis is not fully understood.[5] Although a strong association exists between chronic pulmonary diseases, chronic kidney disease, and cirrhosis, the pathophysiologic mechanisms of these associations remain unclear.[3] In contrast, SRMD occurs primarily in the stomach of critically ill patients (see Table 51-1).[2]

TABLE 51-2

Potential Causes of Peptic Ulcer

Common causes
Helicobacter pylori infection
NSAIDs
Critical illness (stress-related mucosal damage)
Uncommon causes of chronic peptic ulcer
Idiopathic (non–*H. pylori*, non-NSAID peptic ulcer)
Hypersecretion of gastric acid (eg, Zollinger-Ellison syndrome)
Viral infections (eg, cytomegalovirus)
Vascular insufficiency (eg, crack cocaine associated)
Radiation therapy
Chemotherapy (eg, hepatic artery infusions)
Infiltrating disease (eg, Crohn's disease)
Roux-en-Y gastric bypass surgery
Diseases and medical conditions associated with chronic peptic ulcer
Cirrhosis
Chronic kidney disease
Chronic obstructive pulmonary disease
Cardiovascular disease
Organ transplantation

NSAIDs, nonsteroidal anti-inflammatory drugs.

EPIDEMIOLOGY

④ The epidemiology of PUD is complicated, and the prevalence is difficult to estimate given the variability in *H. pylori* infection, NSAID use, and cigarette smoking. In addition, endoscopy, radiology, symptoms, or other methods have different sensitivity and specificity to detect ulcers.[2] Gastroduodenal ulcers occur in 0.1% to 0.3% of the general population annually, and the lifetime prevalence of PUD is between 5% and 10%.[3] The prevalence and incidence of PUD in the United States has decreased, reflecting improvements in drug therapy, the dramatic shift to ambulatory management, and changes in the criteria and coding system for mortality and hospitalization data. Mortality, hospitalization, and emergency department and ambulatory care visits have declined, but 30-day readmissions for upper GI hemorrhage have increased.[6] Mortality rates are higher among those 65 years and older and in males compared to females.[6] PUD remains a common GI disease, resulting in impaired quality of life, work loss, and high-cost medical care.

⑦ The prevalence of *H. pylori* varies by geographic location, resource limitations, ethnicity, and age. In the United States and other industrialized countries, *H. pylori* prevalence has declined with successive birth cohorts and is thought to correlate with improved hygiene and living conditions compared with developing countries.[7,8] In the United States *H. pylori* prevalence is approximately 30% to 40%, but it is much higher in adults older than 60 years (50%-60%) than in children younger than 12 years (10%-15%). The rate of *H. pylori* acquisition in children is declining due to improved environmental conditions in Western populations, but maternal colonization remains an important transmission factor. Disparities in *H. pylori* prevalence continue to exist among Black and Hispanic persons with infection rates approximately two to three times that of non-Hispanic White persons.[8,9] Adults with some college education have reduced prevalence of *H. pylori*, probably related to improved access to resources and living conditions.[9] Infection rates do not differ with gender or smoking status. Among Hispanic persons overall *H. pylori* seroprevalence was 38% in US born and 62% among non-US born individuals.[10]

Nonsteroidal Anti-Inflammatory Drugs

Gastroduodenal lesions including erosions, petechiae, and ulcers are visible upon endoscopy in an estimated 30% to 50% of chronic NSAID users. In most cases, the gastric mucosa adapts, and no clinical manifestations are observed. NSAIDs and low-dose aspirin increase the relative risk of PUD by an estimated 2.7 and 1.7 times, respectively. Despite the introduction of gastroprotective medications, NSAIDs represent an important cause of morbidity and mortality. NSAIDs and low-dose aspirin contribute to significant GI events, including ulceration and bleeding, in 122 per 100,000 persons/year, and 5% of deaths result from upper GI complications. Low-dose aspirin represents approximately 10% of all complications and deaths.[12]

ETIOLOGY

H. pylori infection and NSAID use are the most common risk factors for PUD. Less common factors, including ZES with hypersecretion of acid (see Table 51-2), can also be involved.[2] Disruptions in normal mucosal defense and healing mechanisms allow acid and pepsin to reach the gastric epithelium.[2] Benign gastric ulcers, erosions, and gastritis can occur anywhere in the stomach, although the antrum and lesser curvature represent the most common locations (see Fig. 51-1). Most duodenal ulcers occur in the first part of the duodenum (duodenal bulb).

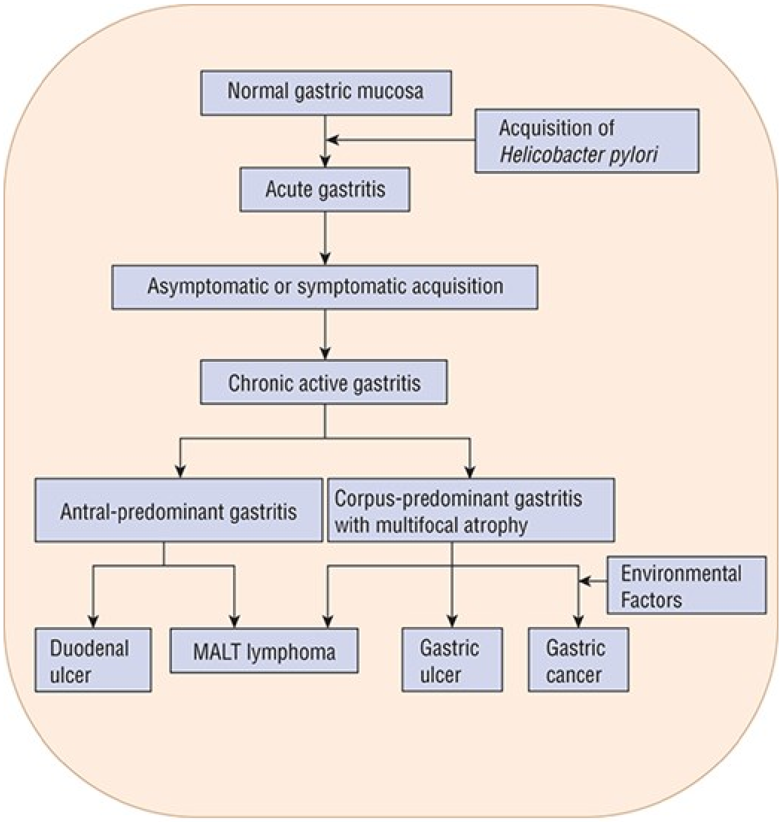
Helicobacter pylori

H. pylori are spiral, microaerophilic, gram-negative bacteria with flagella that have urease, catalase, and oxidase activity. These factors allow the bacterium to survive in the acidic environment of the stomach. Bacterial urease converts urea to ammonia that neutralizes gastric acid, thereby alkalinizing the microenvironment. Catalase activity enables the bacterium to survive reactive oxidation by phagocytes attempting to kill the organism, but the resulting inflammation damages the gastric epithelial lining allowing *H. pylori* to thrive. Bacterial flagella facilitate the initial infection and allows for colonization of the gastric mucosa.[13] *H. pylori* is primarily transmitted via person-to-person routes by either gastro–oral (vomitus) or fecal–oral (diarrhea) contact. Risk factors for acquiring *H. pylori* include close contact within households, low income status, and country of origin.[2,8]

H. pylori infection can cause both acute and chronic gastritis in infected individuals and is associated with multiple GI complications. PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (Fig. 51-2) have all been linked to *H. pylori* infection.[2,7,8] Most infected individuals remain asymptomatic, but 10% to 20% will develop PUD during their lifetime and about 1% will develop gastric cancer. Environmental factors, host genetics, and *H. pylori* strain virulence factors play an important role in the pathogenesis of PUD and gastric cancer.[3] *H. pylori* infection increases the risk of GI bleeding and peptic ulcers by threefold to sevenfold.[8] No specific link has been established between *H. pylori* and dyspepsia, non-ulcer dyspepsia (NUD), or gastroesophageal reflux disease (GERD).[8] However, some patients with dyspepsia and NUD have symptom improvement from *H. pylori* eradication. Conversely, eradication of *H. pylori* may worsen GERD symptoms in some patients, but eradication should be attempted due to the known gastric cancer risk. *H. pylori* is also associated with iron deficiency anemia, although the benefit of eradication remains unknown.[8]

FIGURE 51-2

The natural history of *Helicobacter pylori* infection in the pathogenesis of gastric ulcer and duodenal ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer.



Normal gastric mucosa
Acquisition of *Helicobacter pylori*
Acute gastritis
Asymptomatic or symptomatic acquisition
Chronic active gastritis
Antral-predominant gastritis
Corpus-predominant gastritis with multifocal atrophy
Environmental Factors
Duodenal ulcer
MALT lymphoma
Gastric ulcer
Gastric cancer

Nonsteroidal Anti-Inflammatory Drugs

Prescription and nonprescription NSAIDs (Table 51-3) are widely used in the United States, and have been linked to PUD. There is overwhelming evidence linking chronic NSAID (including low-dose aspirin) use to upper GI tract injury, PUD, gastritis, and superficial erosion.[2,14,15] In susceptible individuals, NSAIDs cause superficial mucosal damage consisting of petechiae (intramucosal hemorrhages) within minutes of ingestion, and progress to erosions with continued use.[11] These lesions typically heal within a few days and rarely cause ulcers or acute upper GI bleeding. NSAID-induced ulcers occur less frequently in the esophagus, small bowel, and colon.[11,12] The mechanisms by which NSAIDs damage the lower GI tract is not clear, but the enteropathy is associated with lower GI bleeding.

TABLE 51-3

Selected NSAIDs and COX-2 Inhibitors

Nonsalicylates[a] Nonselective (traditional) NSAIDs: indomethacin, piroxicam, ibuprofen, naproxen, sulindac, ketoprofen, ketorolac, flurbiprofen, diclofenac Selective COX-2 inhibitors: etodolac, nabumetone, meloxicam, celecoxib, rofecoxib,[b] valdecoxib[b]
Salicylates Acetylated: aspirin Nonacetylated: salsalate, trisalicylate

COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

[a] Based on COX-1-to-COX-2 selectivity ratio.

[b] Withdrawn from US market.

Table 51-4 lists the risk factors associated with NSAID-induced ulcers and upper GI complications. Combinations of factors confer an additive risk.[2,12,16-19] Advanced age is an independent risk factor, and the incidence of NSAID-induced ulcers increases linearly with the age of the patient.[2] The high incidence of ulcer complications in older individuals may be explained by age-related changes in gastric mucosal defense. The relative risk of NSAID complications is increased for patients with a previous peptic ulcer and may be as high as 14-fold in those with a history of an ulcer-related complication.[2,18] Although the risk of ulcer complications is greatest during the first few months after initiating continuous NSAID therapy, it does not vanish with long-term treatment.[20]

TABLE 51-4

Risk Factors Associated with NSAID-Induced Ulcers and Upper GI Complications[a]

- Age >65
- Previous peptic ulcer
- Previous ulcer-related upper GI complication
- High-dose NSAIDs
- Multiple NSAID use
- Selection of NSAID (eg, COX-1 vs COX-2 inhibition)
- NSAID-related dyspepsia
- Aspirin (including cardioprotective dosages)
- Concomitant use of
    - Low-dose aspirin
    - Oral bisphosphonates (eg, alendronate)
    - Systemic corticosteroids
    - Anticoagulant or coagulopathy
    - Antiplatelet drugs (eg, clopidogrel)
    - Selective serotonin reuptake inhibitor
- Chronic debilitating disorders (eg, cardiovascular disease, rheumatoid arthritis)
- *Helicobacter pylori* infection
- Cigarette smoking
- Alcohol consumption

COX-2, cyclooxygenase-2; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

[a] Combinations of risk factors are additive.

Data from References 2,18–20.

NSAID ulcers and related complications are dependent upon the dose, duration of use, and type of NSAID. Although dose is important, low doses of nonprescription NSAIDs and low cardioprotective dosages of aspirin (81-325 mg/day) increase risk of ulcer formation.[2,3,12,17,20] Factors such as NSAID potency, longer duration of effect, and a greater propensity to inhibit cyclooxygenase-1 (COX-1) versus cyclooxygenase-2 (COX-2) isoenzymes are associated with increased risk (see Table 51-3).[2,12,20] NSAID-related dyspepsia, in itself, does not correlate directly with mucosal injury or clinical events. However, new-onset dyspepsia, changes in severity, or dyspepsia not relieved by antiulcer medications may suggest an ulcer or ulcer complication.[2] Nonacetylated salicylates (eg, salsalate) may be associated with decreased GI toxicity.[1,11,21] Buffered or enteric-coated aspirin confers no added protection from upper GI events.[12] NSAID ulcer and GI complication risk are increased with the use of multiple NSAIDs or the concomitant use of low-dose aspirin, oral bisphosphonates, systemic corticosteroids, anticoagulants, antiplatelet drugs, and selective serotonin reuptake inhibitors.[17,19,21] The risk of an ulcer-related GI complication is 10-fold greater when an NSAID or COX-2 inhibitor (see Table 51-3) is coadministered with low-dose aspirin than when either drug is taken alone.[3] The NSAID may also reduce the antiplatelet effects of aspirin, although NSAIDs vary in their effects on platelet function. Corticosteroids, when used alone, do not potentiate the risk of ulcer or complications, but the relative risk is increased twofold in corticosteroid users who are also taking concurrent NSAIDs.[2] The relative risk of GI bleeding increases up to 20-fold when NSAIDs are taken concomitantly with anticoagulants (eg, warfarin) and up to sixfold with the concurrent use of serotonin reuptake inhibitors.[21,22] Coadministration of aspirin with clopidogrel or an anticoagulant increases the risk of GI bleeding compared with either agent taken alone.[15,23]

H. pylori and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and appear to have additive effects.[8] Thus, the incidence of peptic ulcer is higher in *H. pylori*–positive individuals who use NSAIDs. Whether *H. pylori* infection is actually a risk factor for NSAID ulcers remains controversial.[8] However, eradication is reported to reduce the incidence of peptic ulcer if undertaken prior to starting the NSAID, but does not reduce the risk for patients who were previously taking an NSAID.[8]

Cigarette Smoking

Cigarette smoking has been linked to PUD, but it is uncertain whether smoking causes peptic ulcers. The prevalence of ulcer disease is higher in current and former smokers (11.4% and 11.5%) compared to those who never smoked (6%). The risk of peptic ulcers is greatest in smokers with a large daily use, but modest when fewer than 10 cigarettes are smoked per day.[27] Cigarette smoking impairs ulcer healing, promotes ulcer recurrence, and increases ulcer risk. However, the underlying mechanisms by which cigarette smoking exerts these adverse effects remain unclear. Possible mechanisms include mucosal ischemia, inhibition of pancreatic bicarbonate secretion, and increases in gastric acid and mucous secretion, but these effects are inconsistent.[28]

Psychological Stress

Psychosocial stress may influence the pathogenesis of PUD, but it can be difficult to determine whether the stressful exposure was present before development of ulceration.[29] Clinical observation suggests that ulcer patients are adversely affected by stressful life events. However, results from controlled trials are conflicting and have failed to document a cause-and-effect relationship. Emotional stress may induce behavioral risks such as smoking and the use of NSAIDs or alter the inflammatory response or resistance to *H. pylori* infection.[29,30] The role of stress and how it affects PUD is complex and probably multifactorial.

Dietary Factors

The effects of diet and nutrition on the pathophysiology PUD is uncertain. Carbonated beverages, coffee, tea, beer, milk, and spices often cause dyspepsia, but they do not appear to increase the risk of PUD.[2] Dietary interventions such as bland or restricted diets do not alter the frequency of ulcer recurrence. Although caffeine is a gastric acid stimulant, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, beer, and wine may also increase gastric acid secretion. In high concentrations, alcohol ingestion is associated with acute gastric mucosal damage and upper GI bleeding; however, there is insufficient evidence to confirm that alcohol causes ulcers.[2]

PATHOPHYSIOLOGY

The pathophysiology of gastric and duodenal ulcers is determined by the imbalance between aggressive (gastric acid and pepsin) and protective (mucosal defense and repair) factors.[2] Gastric acid is secreted by the parietal cells, which contain receptors for histamine, gastrin, and acetylcholine.[2] Acid (as well as *H. pylori* infection and NSAID use) is an independent factor that contributes to the disruption of mucosal integrity.[2] Acid secretion is increased in patients with duodenal ulcers and may be a consequence of *H. pylori* infection.[31] In contrast, patients with gastric ulcers usually have normal or reduced rates of acid secretion (hypochlorhydria).

The amount of acid secreted under basal or fasting conditions is referred to as basal acid output (BAO); after maximal stimulation, maximal acid output (MAO). Basal and maximal acid secretion varies with time of day and the individual's psychological state, age, gender, and health status. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning.[2] An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES.

Pepsin is an important enzyme cofactor in the proteolytic activity involved in ulcer formation. Pepsinogen, the inactive precursor of pepsin, is secreted by the chief cells in the gastric fundus (see Fig. 51-1). Pepsin activity is determined by pH as it is activated by acid pH (optimal pH of 1.8-3.5), reversibly inactivated at pH 4, and irreversibly destroyed at pH 7.[2]

Mucus and bicarbonate secretion, intrinsic epithelial cell defense, and mucosal blood flow protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.[2] The viscous nature and near-neutral pH of the mucus–bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. Mucosal repair after injury is related to epithelial cell restitution, growth, and regeneration. Endogenous prostaglandins' (PGs) production facilitate mucosal integrity and repair. The term *cytoprotection* is often used to describe this process, but *mucosal* *defense* and *mucosal protection* are more accurate terms, as PGs prevent deep mucosal injury and not superficial damage to individual cells.[11] Gastric hyperemia and increased PG synthesis characterize adaptive cytoprotection, the short-term adaptation of mucosal cells to mild topical irritants that enables the stomach to initially withstand the damaging effects of irritants. Alterations in mucosal defense that are induced by *H. pylori* or NSAIDs are the most important cofactors in the formation of peptic ulcers.[11,32]

Helicobacter pylori

In infected people, *H. pylori* resides between the gastric mucus layer and surface epithelial cells, or any location where gastric-type epithelium is found. The bacterium binds to gastric-type epithelium by adherence pedestals, which prevent the organism from being shed during cell turnover and mucus secretion. Colonization of the antrum and corpus (body) of the stomach is associated with gastric ulcer and cancer. Antral organisms colonize gastric tissue that develops in the duodenum secondary to changes in gastric acid or bicarbonate secretion leading to duodenal ulcer (see Fig. 51-2). Although *H. pylori* causes chronic gastric mucosal inflammation in all infected individuals, only a minority actually develop an ulcer or gastric cancer. The difference in the diverse clinical outcomes is related to variations in bacterial pathogenicity and host susceptibility.

Bacterial enzymes (urease, lipases, and proteases), bacterial adherence, and *H. pylori* virulence factors produce gastric mucosal injury. Lipases and proteases degrade gastric mucus, ammonia produced by urease may be toxic to gastric epithelial cells, and bacterial adherence enhances the uptake of toxins into gastric epithelial cells. *H. pylori* induces gastric inflammation by altering the host inflammatory response and damaging epithelial cells directly by cell-mediated immune mechanisms or indirectly by activated neutrophils or macrophages attempting to phagocytize bacteria or bacterial products. However, *H. pylori* strains are genetically diverse and account for differences in adaptation within the human host. Two of the most important are cytotoxin-associated gene protein (CagA) and vacuolating cytotoxin (VacA). About 60% of *H. pylori* strains in the United States possess CagA, but CagA-positive strains increase the risk for severe PUD, gastritis, and gastric cancer compared with CagA-negative strains. The VacA gene codes for the VacA cytotoxin, a vacuolating toxin. Although VacA is present in most *H. pylori* strains, strains vary in cytotoxicity and increased risk for peptic ulcer and gastric cancer. Host polymorphisms are important markers of disease susceptibility and may identify high-risk patients.[32,33]

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs, including aspirin (see Table 51-3), cause gastric mucosal damage by local and systemic mechanisms, but systemic inhibition of endogenous mucosal PG synthesis is believed to be the primary mechanism.[20] The onset of injury is initiated by the acidic properties of many of the NSAIDs, while systemic inhibition of the protective PGs limits the ability of the mucosa to defend against injury and thus plays the predominant role in the development of gastric ulcer.[20] Acidic NSAIDs (eg, aspirin) have topical irritant properties and they decrease the hydrophobicity of the mucous gel layer in the gastric mucosa. Most non-aspirin NSAIDs have topical irritant effects, but aspirin is the most damaging. Although NSAID prodrugs, enteric-coated aspirin tablets, salicylate derivatives, and parenteral or rectal preparations are associated with less acute gastric mucosal injury, they can cause ulcers and related GI complications because of systemic inhibition of endogenous PGs.

COX is the rate-limiting enzyme in the conversion of arachidonic acid to PGs and is inhibited by NSAIDs (Fig. 51-3). Two similar COX isoforms have been identified: COX-1 is found in most body tissue, including the stomach, kidney, intestine, and platelets; COX-2 is undetectable in most tissues under normal physiologic conditions, but its expression can be induced during acute inflammation and arthritis (Fig. 51-4). COX-1 produces protective PGs that regulate physiologic processes such as GI mucosal integrity, platelet homeostasis, and renal function. COX-2 is induced (unregulated) by inflammatory stimuli such as cytokines and produces PGs involved with inflammation, fever, and pain. It is also constitutionally expressed in organs such as the brain, kidney, and reproductive tract. Adverse effects (eg, GI or renal toxicity) of NSAIDs are primarily associated with the inhibition of COX-1, whereas anti-inflammatory actions result primarily from NSAID inhibition of COX-2.[11]

The COX-1-to-COX-2 inhibitory ratio determines the relative GI toxicity of a specific NSAID. Nonselective NSAIDs, including aspirin (see Table 51-3), inhibit both COX-1 and COX-2 to varying degrees and are associated with an increased propensity to cause gastric ulcers. In contrast, the selective COX-2 inhibitors preferentially inhibit COX-2 in vitro resulting in a reduced risk of ulcers and related GI complications (see Table 51-3). The selectivity for the COX-2 isoenzyme varies among NSAIDs. Celecoxib, meloxicam, etodolac, and nabumetone are considered only partially selective and have more risk of GI complications compared to rofecoxib and valdecoxib.[34] The addition of aspirin to a selective COX-2 inhibitor reduces its ulcer-sparing benefit and increases ulcer risk.[12] Aspirin and non-aspirin NSAIDs irreversibly inhibit platelet COX-1, resulting in decreased platelet aggregation and prolonged bleeding times, thereby increasing the potential for upper and lower GI bleeding. Coadministration of NSAIDs may reduce the antiplatelet effects of aspirin. Clopidogrel, prasugrel, ticagrelor, and related medications that affect platelet aggregation do not cause ulcers, per se, but may impair healing of gastric erosions leading to ulceration and bleeding.[15,25,26]

Complications

The most serious, life-threatening complications of chronic PUD are upper GI bleeding, perforation, and obstruction.[2] Bleeding peptic ulcers, caused by the erosion of an ulcer into an artery, are the most common cause of non-variceal upper GI bleeding, occurring in 26% to 59% of patients.[35] It may be occult (hidden) and insidious or may present as melena (black-colored that combine clarithromycin with amoxicillin stools) or hematemesis (vomiting of blood). NSAID use (especially in older adults) is the most important risk factor for upper GI bleeding. Mortality is highest in patients with uncontrolled bleeding or who have a rebleeding event after the initial bleeding has stopped (see section “Upper Gastrointestinal Bleeding” below).[35]

Gastric perforation into the peritoneal cavity is the second most common ulcer-related complication, occurring in 4 to 14 cases per 100,000 patients.[36] Depending on location, the ulcer may penetrate into an adjacent structure (pancreas, biliary tract, or liver) rather than opening freely into a cavity. Although the incidence of perforated peptic ulcers has decreased with the availability of PPIs, the mortality and morbidity remain high. Mortality from perforated ulcers is five times higher compared with bleeding peptic ulcer and 30-day mortality is approximately 24%. Older patients and those with comorbidities have a worse prognosis.[36] The pain of perforation is usually sudden, sharp, and severe, beginning first in the epigastrium, but quickly spreading over the entire abdomen. Most patients experience ulcer symptoms prior to perforation; however, older patients who experience perforation in association with NSAID use may be asymptomatic. The duodenum can be narrowed due to chronic inflammation and scaring from ulcers, resulting in gastric outlet obstruction. Although gastric outlet obstruction is rare, patients often present with severe vomiting and hematemesis.[37] Perforation, penetration, and gastric outlet obstruction occur most often with long-standing PUD.

CLINICAL PRESENTATION

Clinical Presentation: Peptic Ulcer Disease (PUD)

There is significant variability in the clinical presentation of PUD depending on the severity of epigastric pain and the presence of complications (Table 51-5). Pain related to duodenal ulcer often occurs 1 to 3 hours after meals and is usually relieved by food, but this is variable. Food may precipitate or accentuate gastric ulcer pain. Antacids usually provide immediate pain relief in most ulcer patients. Pain usually diminishes or disappears during treatment; however, recurrence of epigastric pain after healing often suggests an unhealed or recurrent ulcer.

TABLE 51-5

Clinical Presentation of PUD

General

- Mild epigastric pain or acute life-threatening upper GI complications

Symptoms

- Abdominal pain that is often epigastric and described as burning but may present as vague discomfort, abdominal fullness, or cramping
- A typical nocturnal pain that awakens the patient from sleep (especially between 12 and 3 AM)
- The severity of ulcer pain varies between patients and may be seasonal, occurring more frequently in the spring or fall; episodes of discomfort usually occur in clusters, lasting up to a few weeks and followed by a pain-free period or remission lasting from weeks to years
- Changes in the character of the pain may suggest the presence of complications
- Heartburn, belching, and bloating often accompany the pain
- Nausea, vomiting, and anorexia are more common for patients with gastric ulcer than with duodenal ulcer but may also be signs of an ulcer-related complication

Signs

- Weight loss associated with nausea, vomiting, and anorexia
- Complications including ulcer bleeding, perforation, penetration, or obstruction

Laboratory tests

- Gastric acid secretory studies
- The hematocrit and hemoglobin are low with bleeding, and stool hemoccult tests are positive
- Tests for *Helicobacter pylori* (see Table 51-6)

Diagnostic tests

- Fiber-optic upper endoscopy (esophagogastroduodenoscopy) detects more than 90% of peptic ulcers and permits direct inspection, biopsy, visualization of superficial erosions, and sites of active bleeding
- Upper GI radiography with barium has been replaced with upper endoscopy as the diagnostic procedure of choice for suspected peptic ulcer

GI, gastrointestinal; PUD, peptic ulcer disease.

The presence or absence of epigastric pain does not define an ulcer and ulcer healing does not necessarily render the patient asymptomatic. Symptoms may remain because of sensitization of afferent nerves in response to mucosal injury. Conversely, the absence of pain does not preclude an ulcer diagnosis, especially in older patients who may present with a “silent” ulcer complication possibly related to differences in the way they perceive pain or the analgesic effect of NSAIDs.

Dyspepsia alone is of little clinical value when assessing subsets of patients who are most likely to have an ulcer. Patients taking NSAIDs often report dyspepsia, but these symptoms do not always correlate with an ulcer. Functional dyspepsia (FD), or nonulcer dyspepsia (NUD), refers to the lack of an ulcer upon endoscopy in a patient with ulcer-like symptoms.[40] *H. pylori* gastritis or duodenitis may cause ulcer-like symptoms in the absence of peptic ulceration. There is no one sign or symptom that differentiates between *H. pylori*–positive and NSAID-induced ulcer.

Diagnosis

Symptoms of PUD are nonspecific and are of limited predictive value for diagnosis. The diagnosis of PUD depends on visualizing the ulcer crater (see Table 51-5).[2,19] Upper endoscopy has replaced radiography as the diagnostic procedure of choice because it provides a more accurate diagnosis and permits direct visualization of the ulcer and implementation of therapeutic maneuvers to control bleeding such as injection of epinephrine or deployment of hemostatic clips.

Tests for *Helicobacter pylori*

The diagnosis of *H. pylori* infection can be made using endoscopic or nonendoscopic tests (Table 51-6). All patients with active PUD, past history of PUD without documentation of prior cure, low-grade gastric MALT lymphoma, or history of endoscopic resection for early gastric cancer should be tested for *H. pylori*.[8] Testing that requires upper endoscopy is invasive, more expensive, and usually requires a mucosal biopsy for histology, culture, or detection of urease activity. The updated Sydney system recommends taking five tissue samples from different sites within the stomach, as patchy distribution of *H. pylori* infection can lead to false-negative results.[41] Because antibiotics, including bismuth salts, and proton pump inhibitors (PPIs) may decrease the sensitivity of rapid urease test, they should be withheld prior to endoscopic testing for 4 weeks and 2 weeks, respectively.[13,42,43] If the patient has been taking these medications, then a gastric biopsy for histology is preferred.[43]

TABLE 51-6

Tests for Detection of *Helicobacter pylori*

Test	Description	Comments
Endoscopic tests		
Histology	Microbiologic examination using various stains	Gold standard; greater than 95% sensitive and specific; permits classification of gastritis; results are not immediate; not recommended for initial diagnosis; tests for active *H. pylori* infection
Culture	Culture of biopsy	Enables sensitivity testing to determine appropriate treatment or antibiotic resistance; 100% specific; results are not immediate; not recommended for initial diagnosis; used after failure of second-line treatment; tests for active *H. pylori* infection
Biopsy (rapid) urease	*H. pylori* urease generates ammonia, which causes a color change	Test of choice at endoscopy; greater than 90% sensitive and specific; easily performed; rapid results (usually within 24 hours); tests for active *H. pylori* infection
Polymerase chain reaction	*H. pylori* DNA detected in gastric tissue	Test is highly specific and sensitive; high rate of false-positives and false-negatives; positive DNA does not directly equate to presence of the organism; considered a research technique
Nonendoscopic tests		
Antibody detection (laboratory-based)	Detects antibodies to *H. pylori* in serum using laboratory-based ELISA tests and latex agglutination techniques	Quantitative; less sensitive and specific than endoscopic tests; more accurate than in office; unable to determine if antibody is related to active or cured infection; antibody titers vary markedly among individuals and take 6 months to 1 year to return to the uninfected range; not affected by PPIs or bismuth; antibiotics given for unrelated indications may cure the infection, but antibody test will remain positive
Antibody detection (can be performed in office or near patient)	Detects IgG antibodies to *H. pylori* in whole blood or finger stick	Qualitative; quick (within 15 minutes); unable to determine if antibody is related to active or cured infection; most patients remain seropositive for at least 6 months to 1 year after *H. pylori* eradication; not affected by PPIs, bismuth, or antibiotics
Urea breath test	*H. pylori* urease breaks down ingested labeled C-urea, patient exhales labeled CO_2	Tests for active *H. pylori* infection; 95% sensitive and specific; results take about 2 days; antibiotics, bismuth, PPIs, and H2RAs may cause false-negative results; withhold PPIs or H2RAs (1-2 weeks) and bismuth or antibiotics (4 weeks) prior to testing; recommended test to confirm posttreatment eradication of *H. pylori*
Fecal antigen	Identifies *H. pylori* antigen in stool by enzyme immunoassay using polyclonal anti–*H. pylori* antibody	Tests for active *H. pylori* infection; sensitivity and specificity comparable to urea breath test when used for initial diagnosis; antibiotics, bismuth, and PPIs may cause false-negative results, but to a lesser extent than with the urea breath test; may be used posttreatment to confirm eradication, but patients may have a reluctance to obtain stool samples

ELISA, enzyme-linked immunosorbent assay; H2RA, H_2-receptor antagonist; PPIs, proton pump inhibitors.

Data from References [13,38,39].

Nonendoscopic tests (urea breath test [UBT], serologic antibody detection tests, and the fecal antigen test) may identify active infection or detect antibodies (see Table 51-6) and are less invasive, more convenient, and less expensive than the endoscopic tests.[43] However, antibody tests do not differentiate between active infection and previously eradicated *H. pylori*.

The UBT is the most accurate noninvasive test and is based on *H. pylori* urease activity.[41] The ^{13}Carbon (nonradioactive isotope) and ^{14}Carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by *H. pylori* (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and excreted in the breath. In addition to being noninvasive, another advantage of UBT over biopsy is that it overcomes the possible sampling error associated with endoscopic biopsy secondary to irregular distribution of *H. pylori*.[41] The fecal antigen test is less expensive and easier to perform than the UBT, and may be useful in children.

Serologic tests are a cost-effective alternative for the initial diagnosis of *H. pylori* infection in the untreated patient. Antibodies to *H. pylori* usually develop about 3 weeks after infection and remain present after successful eradication. Therefore, serology should not be used to confirm *H. pylori* eradication. Office-based tests are less expensive, widely available, and provide rapid results, but the results are less accurate and more variable than the laboratory-based tests.

Testing for *H. pylori* is only recommended if eradication therapy is planned. Serologic antibody testing is a reasonable choice if endoscopy is not planned. The diagnostic accuracy of *H. pylori* tests for patients with an active bleeding ulcer has been questioned because of the potential for false-negative results. However, endoscopic biopsy-based tests such as the rapid urease test have a high degree of specificity in these patients (see section "Peptic Ulcer–Related Bleeding").[8]

Confirmation of eradication is indicated posttreatment whenever *H. pylori* is identified and treated.[8] Endoscopic biopsy-based tests, UBT and fecal antigen are the recommended tests to confirm *H. pylori* eradication. Testing for eradication should be delayed at least 4 weeks after the completion of antibiotics and after PPI has been discontinued for 2 weeks to avoid confusing bacterial suppression with eradication.[8]

Clinical Course and Prognosis

Untreated PUD is characterized by periods of exacerbations and remissions.[2] Ulcer pain is usually recognizable and episodic, but symptoms are varied, especially in older adults and for patients taking NSAIDs. Antiulcer medications, including the histamine-2 receptor antagonists (H2RAs), PPIs, and sucralfate, relieve symptoms, accelerate ulcer healing, and reduce the risk of ulcer recurrence, but they do not cure the disease. Both duodenal and gastric ulcers recur unless the underlying cause (*H. pylori* or NSAID) is addressed. Successful *H. pylori* eradication markedly decreases ulcer recurrence and complications. Prophylactic co-therapy or a COX-2 inhibitor decreases the risk of upper GI events for patients who are taking NSAIDs. GI bleeding, perforation, and obstruction remain troublesome complications of chronic PUD. Mortality for patients with gastric ulcer is slightly higher than in duodenal ulcer and the general population. The development of gastric cancer in *H. pylori*–infected individuals is a slow process that occurs over 20 to 40 years and is associated with a lifetime risk of less than 1%.[1]

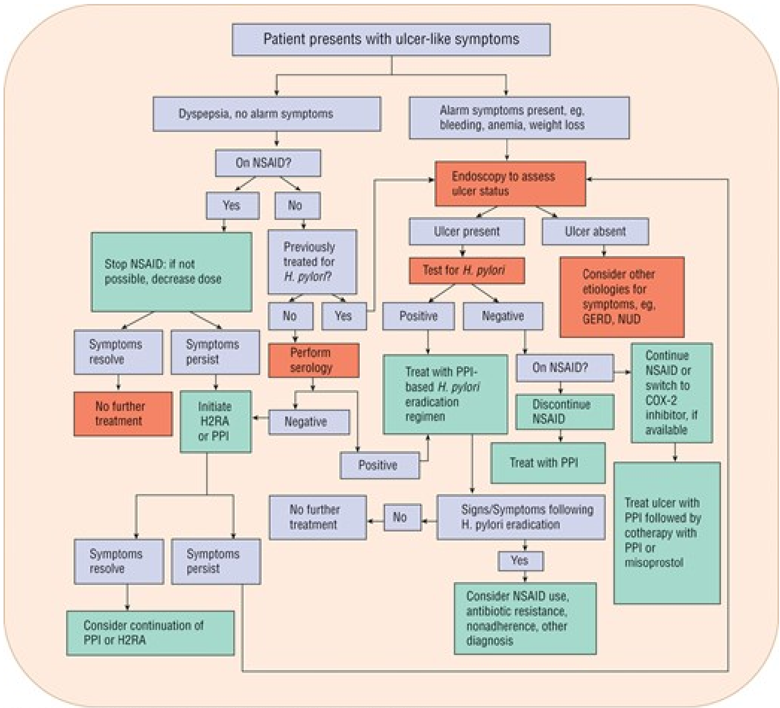
TREATMENT

General Approach to Treatment

The treatment of PUD varies depending on the etiology of the ulcer (*H. pylori* or NSAID), whether the ulcer is initial or recurrent, and whether complications have occurred (Fig. 51-5). Treatment is aimed at relieving ulcer pain, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. Antimicrobials in combination with antisecretory drugs (PPIs or H2RAs) eradicate *H. pylori* infection allowing for ulcer healing and relief of ulcer symptoms. PPIs accelerate ulcer healing and provide more effective relief of symptoms compared to H2RAs or sucralfate, and are preferred for healing *H. pylori*–negative NSAID-induced ulcers. In patients taking NSAIDs for pain, alternative agents such as acetaminophen or nonacetylated salicylate (eg, salsalate) should be used for relief of pain when possible. Patients requiring continuation of NSAID therapy at high risk of developing peptic ulcers should be switched to a selective COX-2 inhibitor NSAID or receive prophylactic co-therapy to reduce ulcer risk and related complications.

FIGURE 51-5

Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. (COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; H2RA, H_2-receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; NUD, nonulcer dyspepsia; PPI, proton pump inhibitor)



Patient presents with ulcer-like symptoms
Dyspepsia, no alarm symptoms
Alarm symptoms present, eg, bleeding, anemia, weight loss
On NSAID?
Yes
No
Endoscopy to assess ulcer status
Stop NSAID: if not possible, decrease dose
Previously treated for H. pylori?
Ulcer present
Ulcer absent
Test for H. pylori
Consider other etiologies for symptoms, eg, GERD, NUD
No
Yes
Positive
Negative
Symptoms resolve
Symptoms persist
Perform serology
Treat with PPI-based H. pylori eradication regimen
On NSAID?
Continue NSAID or switch to COX-2 inhibitor, if available
No further treatment
Initiate H2RA or PPI
Negative
Discontinue NSAID
Positive
Treat with PPI
Treat ulcer with PPI followed by cotherapy with PPI or misoprostol
No further treatment
No
Signs/Symptoms following H. pylori eradication
Yes
Symptoms resolve
Symptoms persist
Consider NSAID use, antibiotic resistance, nonadherence, other diagnosis
Consider continuation of PPI or H2RA

Dietary modifications can be considered for patients unable to tolerate certain foods and beverages. Lifestyle modifications such as reducing stress and smoking cessation are encouraged. Surgery is rarely necessary and is used only for patients with ulcer-related complications.[2,19]

Desired Outcome

The goal for patients with PUD, regardless of the cause, is to relieve ulcer symptoms, heal the ulcer, and prevent recurrence. In patients with NSAID-induced ulcer, withdrawal of the offending agent and careful consideration of the need for continued NSAID therapy can reduce the risk of ulcer recurrence. In *H. pylori*–positive patients with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication, the goal is to eradicate *H. pylori*, heal the ulcer, and cure the disease. Successful eradication heals ulcers and reduces the risk of recurrence for most patients.

Nonpharmacologic Therapy

① Lifestyle modifications, including stress reduction and smoking cessation, should be implemented in patients with PUD. There is no specific recommended diet for patients with current or history of PUD; however, patients should avoid foods and beverages (eg, spicy foods, caffeine, and alcohol) that cause dyspepsia or that exacerbate ulcer symptoms. Emergent surgery for patients with ulcer-related complications, including bleeding, perforation, or obstruction, is necessary in 5% to 10% of hospitalized patients.[2]

Pharmacologic Therapy

Recommendations

② Table 51-7 presents guidelines for the eradication of infection in *H. pylori*–positive individuals. Table 51-8 lists regimens used to eradicate *H. pylori* infection.

TABLE 51-7

Guidelines for the Eradication of *Helicobacter pylori* Infection

Indications for treatment of *H. pylori* infection

- Established indications for the treatment of *H. pylori* include active PUD, past history of PUD (unless eradication previously documented), MALT lymphoma, or after endoscopic resection of gastric cancer
- Controversial indications for the treatment of *H. pylori* infection include individuals with functional dyspepsia, gastroesophageal reflux disease, unexplained iron deficiency anemia, or idiopathic thrombocytopenic purpura; individuals taking long-term low-dose aspirin or initiating chronic treatment with NSAIDs; and individuals at high risk for gastric cancer

Initial treatment of *H. pylori* infection

- Bismuth quadruple therapy and concomitant (non-bismuth quadruple therapy), both administered for 10-14 days, are recommended first-line treatments
- In penicillin-allergic patients, bismuth quadruple therapy is the preferred initial treatment. Consider referral for allergy testing in patients who fail initial therapy, since many patients who report penicillin allergy are not truly allergic
- Alternate initial therapies (conditionally recommended) include: Sequential, hybrid, levofloxacin-triple, levofloxacin sequential, and LOAD therapies (see Table 51-8 for a full description)

Eradication of *H. pylori* after initial treatment failure

- Bismuth quadruple therapy or levofloxacin regimens are preferred if the patient received initial treatment with clarithromycin
- Clarithromycin- or levofloxacin-containing regimens are preferred if patients received initial treatment with bismuth quadruple therapy
- Selection of the optimal salvage regimen should be based on local antibiotic resistance profile, if available, and the patient's prior antibiotic history

MALT, mucosa-associated lymphoid tissue; NSAIDs, nonsteroidal anti-inflammatory drugs; PPI, proton pump inhibitor.

Data from References 8,13,39.

TABLE 51-8

Drug Regimens Used to Eradicate *Helicobacter pylori*

Regimen	Duration	Drug #1	Drug #2	Drug #3	Drug #4
Proton pump inhibitor–based triple therapy[a]	14 days	PPI once or twice daily[b]	Clarithromycin 500 mg twice daily	Amoxicillin 1 g twice daily *or* metronidazole 500 mg twice daily	
Bismuth quadruple therapy[a]	10-14 days	PPI or H2RA once or twice daily[b,c]	Bismuth subsalicylate[d] 525 mg four times daily	Metronidazole 250-500 mg four times daily	Tetracycline 500 mg four times daily
Non-bismuth quadruple or “concomitant” therapy[e]	10-14 days	PPI once or twice daily on days 1-10[b]	Clarithromycin 250–500 mg twice daily on days 1-10	Amoxicillin 1 g twice daily on days 1-10	Metronidazole 250-500 mg twice daily on days 1-10
Sequential therapy[e]	10 days	PPI once or twice daily on days 1-10[b]	Amoxicillin 1 g twice daily on days 1-5	Metronidazole 250-500 mg twice daily on days 6-10	Clarithromycin 250-500 mg twice daily on days 6-10
Hybrid therapy[e]	14 days	PPI once or twice daily on days 1-14[b]	Amoxicillin 1 g twice daily on days 1-14	Metronidazole 250–500 mg twice daily on days 7-14	Clarithromycin 250-500 mg twice daily on days 7-14
Levofloxacin triple	10-14 days	PPI twice daily	Levofloxacin 500 mg daily	Amoxicillin 1 g twice daily	
Levofloxacin sequential	10 days	PPI twice daily on days 1-10	Amoxicillin 1 g twice daily on days 1-5	Levofloxacin 500 mg once daily on days 6-10	Metronidazole 500 mg twice daily on days 6-10
Levofloxacin, omeprazole, nitazoxanide, doxycycline (LOAD)	7-10 days	Levofloxacin 250 mg once daily	Omeprazole (or other PPI) at high dose once daily	Nitazoxanide (Alinia) 500 mg twice daily	Doxycycline 100 mg once daily
Rifabutin-based triple therapy	14 days	Omeprazole 40 mg every 8 hours	Amoxicillin 1 g every 8 hours	Ribabutin 50 mg every 8 hours	

H2RA, H_2-receptor antagonist; PPI, proton pump inhibitor.

[a] Although treatment is minimally effective if used for 7 days, 10 to 14 days is recommended. The antisecretory drug may be continued beyond antimicrobial treatment for patients with a history of a complicated ulcer, for example, bleeding, or in heavy smokers.

[b] Standard PPI peptic ulcer healing dosages given once or twice daily.

[c] Standard H2RA peptic ulcer healing dosages may be used in place of a PPI.

[d] Bismuth subcitrate potassium (biskalcitrate) 140 mg, as the bismuth salt, is contained in a prepackaged capsule (Pylera), along with metronidazole 125 mg and tetracycline 125 mg; three capsules are taken with each meal and at bedtime; a standard PPI dosage is added to the regimen and taken twice daily. All medications are taken for 10 days.

[e] Requires validation as first-line therapy in the United States.

Data from References 4,8,13,39,44.

③ The most cost-effective drug regimen should be used whenever feasible. Several first-line therapies are recommended, but bismuth quadruple therapy for 10 to 14 days has the strongest level of recommendation and should be used preferentially. Another recommended first-line therapy is concomitant therapy (PPI, clarithromycin, amoxicillin, and metronidazole) for 10 to 14 days. Clarithromycin triple therapy is no longer recommended in areas where *H. pylori* resistance exceeds 15%, which includes all of North America.[45] If a second course of treatment is required, the salvage regimen should contain different antibiotics and patients with reported penicillin allergy should be considered for allergy testing.

H. pylori testing should be performed in patients with NSAID-induced ulcers to determine their status. If *H. pylori*–positive, treatment should be initiated with a recommended first-line regimen (see Table 51-8). If *H. pylori*–negative, the NSAID should be discontinued, and the patient treated with a PPI, H2RA, or sucralfate (see Table 51-9). If the NSAID is continued, co-therapy with a PPI or misoprostol should be implemented. Patients at highest risk of recurrent ulcers or ulcer-related complications should be switched to a selective COX-2 inhibitor.

TABLE 51-9

Drug Dosing Table

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Proton Pump Inhibitors					
Omeprazole, sodium bicarbonate	Prilosec, Zegerid	40 mg daily	20-40 mg/day	Consider adjustment for hepatic disease	Pregnancy Category C
Lansoprazole	Prevacid, various	30 mg daily	15-30 mg/day	Consider adjustment for hepatic disease	Pregnancy Category B
Rabeprazole	Aciphex	20 mg daily	20-40 mg/day	Use with caution in severe hepatic disease	Pregnancy Category B
Pantoprazole	Protonix, various	40 mg daily	40-80 mg/day	Consider adjustment for severe hepatic disease	Pregnancy Category B
Esomeprazole	Nexium	40 mg daily	20-40 mg/day	Limit dose to 20 mg/day in severe hepatic disease	Pregnancy Category B
Dexlansoprazole	Dexilant	30-60 mg daily	30-60 mg/day	Consider dose limit of 30 mg/day in moderate hepatic impairment, dose not established in severe hepatic disease	Pregnancy Category B
H2-Receptor Antagonists					
Cimetidine	Tagamet, various	300 mg four times daily, 400 mg twice daily, or 800 mg at bedtime	800-1,600 mg/day in divided doses	Adjust dose for renal and severe hepatic impairment	Pregnancy Category B
Famotidine	Pepcid,	20 mg twice daily, or 40	20-40	Adjust dose for renal impairment	Pregnancy Category B

	various	mg at bedtime	mg/day		
Nizatidine	Axid, various	150 mg twice daily, or 300 mg at bedtime	150-300 mg/day	Adjust dose for renal impairment	Pregnancy Category B
Ranitidine[a]	Zantac, various	150 mg twice daily, or 300 mg at bedtime	150-300 mg/day	Adjust dose for renal impairment	Pregnancy Category B
Mucosal Protectants					
Sucralfate	Carafate, various	1 g four times daily, or 2 g twice daily	2-4 g/day		Aluminum may accumulate in renal failure, Pregnancy Category B
Misoprostol	Cytotec	100-200 mcg four times daily	400-800 mcg/day		Pregnancy Category X

[a]Ranitidine products are no longer available in the United States.

Data from References 2,4.

Maintenance therapy with a PPI or H2RA should be limited to high-risk patients with ulcer complications, patients who fail eradication, and those with *H. pylori*–negative ulcers. Treatment failure is associated with poor medication adherence, antimicrobial resistance, NSAID use, cigarette smoking, acid hypersecretion, or tolerance to the antisecretory effects of an H2RA.

Treatment of *Helicobacter pylori*–Positive Ulcers

This chapter focuses on the eradication of *H. pylori* in adults. A discussion of the treatment of *H. pylori* infection in children is found elsewhere.[46]

Ideally, treatment of *H. pylori*–positive PUD should be highly effective, free of significant side effects, easy to adhere to, and cost-effective. Unfortunately, available treatments are lacking in one or more of these areas, making it difficult to identify an ideal treatment regimen.[2] The most important predictor of *H. pylori* eradication is antimicrobial resistance.[8] Additional factors that may also be important include duration of therapy, medication adherence, and genetic polymorphism.[47] The initial eradication regimen offers the highest likelihood of eradication; therefore, selection of an appropriate first-line regimen is important. No available regimen offers assurance of 100% eradication, and few recommended regimens consistently exceed 90% eradication in studies.[8,48]

Table 51-8 summarizes available first-line drug regimens with antisecretory drug, usually a PPI, in combination with multiple antibiotics and/or bismuth. The use of only one antibiotic is associated with a higher rate of antimicrobial resistance and is therefore not recommended. Clarithromycin, amoxicillin, metronidazole, and tetracycline have in vitro activity against *H. pylori* and have been extensively studied in various combinations and dosing strategies. Bismuth salts have a topical antimicrobial effect. Lesser studied antibiotics with activity include rifabutin, doxycycline, and minocycline.[49,50]

Antisecretory drugs hasten ulcer healing, relieve pain in patients with an active ulcer, and enhance antibiotic activity by increasing intragastric pH and by decreasing intragastric volume, thereby enhancing the topical antibiotic concentration. *PPIs generally produce higher H. pylori eradication rates and are preferred over H2RA.* The PPI is an integral part of the regimen and should be taken 30 to 60 minutes before a meal (see Table 51-8). Prolonged PPI treatment beyond 2 weeks after eradication is usually not necessary for ulcer healing. A single daily dose of a PPI may be less effective than a twice-daily dose. Substitution of one PPI for another is acceptable and does not enhance or diminish *H. pylori* eradication.[51] An H2RA should not be substituted for a PPI unless there are significant tolerability issues. Pretreatment with a PPI does not influence *H. pylori* eradication regardless of the pretreatment duration.[52]

Proton Pump Inhibitor–Based Three-Drug Regimens

PPI-based triple therapy remains an option in regions where clarithromycin resistance is <15% and no prior macrolide exposure is documented, but these regimens are no longer recommended in North America due to high clarithromycin resistance rates.[8,39,48,53] If use is indicated, regimens that combine clarithromycin with amoxicillin or metronidazole are more effective than the amoxicillin–metronidazole regimen. The clarithromycin–amoxicillin regimen is preferred initially (see Table 51-7), but metronidazole can be substituted for amoxicillin for penicillin-allergic patients unless alcohol is consumed.[8,39] In most cases, increasing the antibiotic dosage does not improve eradication rates. Since the first treatment regimen offers the highest probability of *H. pylori* eradication, the recommended duration of triple therapy is 14 days.[8] Shorter treatment durations, including 7- to 10-day courses, should no longer be used because of increased resistance and lower overall eradication rates.[8]

Bismuth-Based Quadruple Therapy

Bismuth-based quadruple therapy (bismuth salicylate, metronidazole, tetracycline, and either a PPI or H2RA) (see Table 51-8) is a recommended first-line option (see Table 51-7), particularly for those patients who are allergic to penicillin.[8] The mean eradication rate for bismuth-based quadruple therapy given for 10 days was 91%, which is considerably higher compared with PPI-based triple therapy.[8] Bismuth quadruple therapy for 10 to 14 days was superior to 7 days of clarithromycin triple therapy (85% vs 73%, RR=1.17).[54] Eradication rates are comparable for different bismuth preparations used (see Table 51-8).[50] All medications except the PPI should be taken with meals and at bedtime. Limitations of this regimen include four times per day dosing, potential for poor medication adherence, and frequent minor side effects.[50]

Sequential Therapy

Sequential therapy is a form of eradication therapy in which the antibiotics are administered in a sequence rather than together.[8,55] The basis for sequential therapy is to initially treat with antibiotics that rarely promote resistance (eg, amoxicillin) to reduce the bacterial load and any preexisting resistant organisms that are susceptible. The second sequence follows with different antibiotics (eg, clarithromycin and metronidazole) to kill any remaining organisms.[8,55,56] See Table 51-8 for a typical treatment regimen. Although this regimen has achieved eradication rates that are superior to the PPI-based three-drug regimens containing clarithromycin,[56] the regimen requires a change in medication mid-treatment, which may contribute to nonadherence. Though promising, the advantages of sequential therapy have yet to be fully validated in the United States, and is only conditionally recommended within guidelines as a first-line *H. pylori* eradication therapy (see Table 51-7).[8]

Non-Bismuth Quadruple “Concomitant” Therapy and Hybrid Therapy

Non-bismuth quadruple therapy, also called “concomitant” therapy, is a regimen with a PPI, amoxicillin, clarithromycin, and metronidazole taken together at standard doses for 10 to 14 days. Hybrid therapy combines the strategies of concomitant and sequential therapy. Patients take dual therapy (PPI and amoxicillin) followed by 7 days of quadruple therapy (PPI, amoxicillin, clarithromycin, and metronidazole). Although clarithromycin resistance may impact efficacy rates, both concomitant and hybrid therapy may be impacted less than clarithromycin triple therapy. Both regimens are first-line alternatives to clarithromycin triple therapy, but there is a lack of evidence in North America with these regimens.[8]

Levofloxacin-Based Therapy

Levofloxacin has been studied as first-line and salvage therapy for *H. pylori* eradication, but data are scarce for levofloxacin-based first-line treatment regimens. Three regimens using levofloxacin have been studied (see Table 51-8). Eradication is similar with 7 days of clarithromycin-based or levofloxacin triple therapy; however, levofloxacin-based triple therapy for 10 to 14 days is superior to clarithromycin triple therapy for 7 days.[54] Levofloxacin sequential therapy has eradication rates higher than pooled clarithromycin-based triple and sequential regimens (87.8% vs 71.1%).[8] A first-line quadruple regimen, termed “LOAD,” is not recommended within the guidelines due to cost and lack of data.[8] Concerns about using fluoroquinolones to treat *H. pylori* include development of resistance and adverse effects (eg, tendonitis and hepatotoxicity).

Probiotics

Probiotics (eg, strains of *Lactobacillus* and *Bifidobacterium*) limit *H. pylori* colonization and when taken as a supplement to antibiotic therapy, increase eradication rates compared to placebo and may reduce the adverse effects of antibiotic eradication therapy.[57,58] However, the administration of probiotics alone does not eradicate *H. pylori* infection. The optimal probiotic strains, dose, timing, and duration has yet to be determined.

Eradication of *Helicobacter pylori* After Initial Treatment Failure

H. pylori eradication is often more difficult after initial treatment fails and successful eradication after retreatment is extremely variable.[8] Treatment failures should be referred to a gastroenterologist for further diagnostic evaluation. Second-line (salvage) treatment should (a) use antibiotics that were not used during initial therapy or recently for another infection; (b) be guided by region-specific or individual antibiotic resistance testing, if available; and (c) use an extended duration of treatment up to 10 to 14 days.[8] Ideally, culture and sensitivity or molecular resistance data would be available to guide salvage regimen selection; however, these modalities may be unavailable (eg, the United States) and empiric treatment decisions are necessary. European guidelines recommend obtaining antimicrobial sensitivity information following the second failed attempt to eradicate *H. pylori*. Preferred regimens are provided in Table 51-7. A 10-day therapy containing PPI, bismuth, tetracycline, and levofloxacin achieved a high eradication rate after failure of first-line treatment with standard clarithromycin triple or non-bismuth quadruple therapy.[59] High-dose dual therapy using amoxicillin plus a PPI with both administered three-to-four times daily for 14 days is an acceptable therapy.[8] Other salvage regimens that include rifabutin are also effective, but these are discussed in more detail elsewhere.[60,61] Penicillin skin testing is now recommended for patients after failing one or two eradication attempts since amoxicillin is an important component of therapy with low prevalence of resistance and many patients reporting penicillin allergy are not truly allergic.[8]

Factors That Predict *Helicobacter pylori* Eradication Outcomes

Factors that predict successful *H. pylori* eradication can be divided into host-related and *H. pylori*-related factors. Medication adherence and pharmacogenomic factors are important host-related considerations, and antibiotic resistance is the most important and consistent predictor of *H. pylori* eradication.[39]

Medication adherence decreases with multiple medications, increased frequency of administration, intolerable adverse effects, and costly drug regimens—all of which can be issues with recommended treatment options. Tolerability varies with different regimens, but common adverse effects include nausea, vomiting, abdominal pain, diarrhea, and taste disturbances (metronidazole and clarithromycin). Adverse effects with metronidazole are dose-related (especially when more than 1 g/day) and include a disulfiram-like reaction with alcohol. Tetracycline may cause photosensitivity and should not be used in children because of possible tooth discoloration. Bismuth salts may cause darkening of the stool and tongue. Antibiotic-associated diarrhea and *Clostridioides difficile*–associated disease can occur. Oral thrush and vaginal candidiasis may also occur.

An increasingly important predictor of eradication is the presence or absence of resistant *H. pylori* strains.[8] The following are worldwide antibiotic resistance rates among *H. pylori* strains ($n = 818$ isolates): clarithromycin (30.8%), metronidazole (30.5%), amoxicillin (2%), tetracycline (0%), and levofloxacin (14.2%).[45] Although amoxicillin and tetracycline resistance remains low in available surveillance, prevalence of clarithromycin resistance exceeding 20% negatively impacts successful empiric *H. pylori* eradication therapy.[53] Increasing clarithromycin resistance may explain the decrease in efficacy of triple therapy clarithromycin-containing regimens. Prior exposure to macrolide antibiotics adversely affected the success of eradication using clarithromycin-based triple therapy.[62] Bismuth-containing, concomitant, or sequential therapies may be preferred in patients with prior macrolide exposure.[8,62] Therefore, prior antibiotic use should prompt consideration for possible *H. pylori* resistance. The clinical importance of metronidazole resistance remains uncertain, as resistance can be overcome by using higher dosages and by combining metronidazole with other antibiotics. Resistance to tetracycline and amoxicillin is uncommon. Resistance to bismuth has not been reported.[8] Although the role of antibiotic sensitivity testing prior to initiating *H. pylori* treatment has not been formally established, molecular-based tests may offer quick and easy determination of *H. pylori* resistance to macrolides and fluoroquinolones allowing optimal regimen selection.[63]

Treatment of Nonsteroidal Anti-Inflammatory Drug–Induced Ulcers

NSAID therapy should be interrupted upon confirmation of an active ulcer. Once stopped, most uncomplicated NSAID ulcers heal with standard 8-week regimens of an H2RA, PPI, or sucralfate (see Table 51-9).[20] Generally, PPIs are preferred due to more rapid symptom relief and ulcer healing. In patients where the NSAID is continued despite ulceration, treatment with a PPI or misoprostol should be initiated.[64] PPIs are the drugs of choice when the NSAID is continued, as potent acid suppression is required to accelerate ulcer healing. PPI treatment duration should be extended 12 weeks if the NSAID must be continued. In addition, consideration should be given to reducing the NSAID dose, switching to acetaminophen or a nonacetylated salicylate, or using a selective COX-2 inhibitor (see Table 51-3). If the ulcer is *H. pylori*–positive, eradication should be initiated with a regimen that contains a PPI.[20]

Prevention of NSAID-Related Peptic Ulcers

Among patients who use NSAIDs, several therapeutic strategies are available to prevent gastroduodenal ulcers and related upper GI complications. These strategies include co-therapy of an NSAID with a PPI, H2RA, or misoprostol; preferential use of a COX-2 selective NSAID; or combination of a gastroprotective agent with a COX-2 selective NSAID (see Table 51-10). COX-2 selective NSAID in combination with a PPI offers the greatest protection against upper GI complications. This regimen is followed in effectiveness by COX-2 selective NSAIDs alone, nonselective NSAIDs with a PPI, and medical co-therapy with misoprostol.[12,65] Unfortunately, these strategies may not eliminate ulcers and complications for patients at the “highest risk.” Nonselective NSAID and co-therapy with an H2RA is effective at preventing duodenal but not gastric ulcers.[12] Selection of a gastroprotective strategy should consider both the GI benefits and the cardiovascular risks associated with NSAIDs.[20] Strategies aimed at reducing the topical irritant effects of nonselective NSAIDs, for example, prodrugs, slow-release formulations, and enteric-coated products, are not effective at preventing ulcers or GI complications.

TABLE 51-10

Potential Risks and Safety Issues Associated with the PPIs

- Gastric cancers or malignancy
  - Carcinoid tumors
  - Atrophic gastritis
  - Adenocarcinoma
- Bacterial overgrowth
  - Increase in *N*-nitroso compounds from ingested nitrates (carcinogenic)
  - Enteric infections (*Clostridioides difficile, Salmonella typhimurium*, and *Campylobacter jejuni*)
  - Community-acquired pneumonia
- Decreased nutrient absorption:
  - Iron
  - Calcium
  - Cyanocobalamin (vitamin B_{12})
  - Magnesium
- Osteoporosis and related fractures
- Chronic kidney disease and acute kidney injury

PPI, proton pump inhibitor.

Data from References [51,79,97].

Misoprostol Co-therapy

Misoprostol, a synthetic analog of prostaglandin E1, has dual gastroprotective effects by improving mucosal blood flow and by stimulating gastric mucous and bicarbonate secretion. It has a short half-life requiring doses to be administered three-to-four times daily. Misoprostol’s efficacy increases with higher doses, with prevention trials demonstrating significantly fewer endoscopically confirmed gastric and duodenal ulcers compared with placebo. Misoprostol also decreases the risk of PUD complications including perforation, gastric outlet obstruction, and bleeding.[66] Misoprostol is associated with high-rates of nausea, diarrhea, and abdominal cramping that increase with the dose, limiting its clinical utility.[3,12]

H2-Receptor Antagonist Co-therapy

Standard doses of H2RA are effective at reducing endoscopically confirmed duodenal ulcers compared to placebo, but higher doses (eg, famotidine 80 mg/day) are needed to prevent gastric ulcers.[19] In both cases, H2RAs are less effective when compared with PPI or misoprostol.[66] For this reason, H2RAs are relegated to second-line therapy for prevention of NSAID-induced gastric ulcer and related complications. Patients at higher risk (eg, prior ulcer or older patients) should receive PPIs preferentially over H2RA.[64] Candidates for H2RA as co-therapy include patients who have significant non-modifiable drug interactions or are intolerant of PPIs or misoprostol.

Proton Pump Inhibitor Co-therapy

④ PPI co-therapy reduces NSAID-related gastric and duodenal ulcer risk and is better tolerated than misoprostol.[12,18,20] PPI co-therapy is more effective than misoprostol and H2RA at preventing NSAID-induced gastric ulcer and related complications.[66]. All PPIs are considered equally effective when used in standard dosages (see Table 51-9) for ulcer prevention. There is not an incremental benefit with higher doses for ulcer prevention, even among higher risk patients (ie, age > 60 years, prior gastric/duodenal ulcer).[67] PPIs reduce the risk of NSAID-related upper GI bleeding, but do not protect against lower GI bleeding.[18]

Cyclooxygenase-2 Inhibitors

COX-2 inhibitors preferentially act on the cyclooxygenase-2 enzyme, exhibiting equivalent anti-inflammatory activity of traditional NSAIDs with a lower risk of gastric or duodenal ulcers. Avoidance of COX-1 isoenzyme inhibition preserves prostaglandin production and its beneficial gastroprotective effects. Celecoxib preferentially inhibits COX-2, but carries the same GI and cardiovascular thrombotic black-box warnings as nonselective NSAIDs. The pooled relative risk for GI bleeding is lower with celecoxib (RR 1.45) compared to nonselective NSAIDs, but it is not without some risk. Gastroprotective benefits of celecoxib are lessened in aspirin users, thus if low-dose aspirin is needed, co-therapy with PPI is necessary and a longer duration of treatment. Thus, the lowest effective celecoxib dose should be used for the shortest duration of time. Dyspepsia and abdominal pain, fluid retention, hypertension, and renal toxicity are associated with the COX-2 inhibitors and nonselective NSAIDs. Patients taking NSAIDs or COX-2 inhibitors should be counseled about signs and symptoms of adverse events, including upper GI bleeding and cardiovascular risks, and what to do should they occur.

COX-2 Inhibitor Versus NSAID Plus PPI

⑤ For high GI risk, low CV risk, *H. pylori*–negative patients, a COX-2 selective NSAID alone is at least as beneficial as a nonselective NSAID plus PPI co-therapy in reducing NSAID-related ulcer complications.[20] However, neither the COX-2 selective NSAID nor the NSAID plus a PPI guarantees elimination of upper GI events for high GI risk patients. Combining a COX-2 selective NSAID with a PPI can be considered for very high GI risk patients as it offers the best protection against PUD complications. Patients with complicated peptic ulcer history or presence of multiple risk factors are candidates for COX-2 selective NSAID combined with a PPI.[20]

Treatment of Non–*Helicobacter pylori*, Non-Nonsteroidal Anti-Inflammatory Drug Ulcers

Peptic ulcers unrelated to *H. pylori* or use of NSAIDs, including low-dose aspirin, are considered a distinct diagnosis and referred to as idiopathic ulcers. In North America, between 11% and 44% of peptic ulcers were determined to be idiopathic.[68] With more effective acid suppressive therapy, the incidence of idiopathic ulcers is believed to be increasing worldwide. Patients with idiopathic ulcer have a worse prognosis due to high relapse rate, recurrent ulcer bleeding, and increased risk of death. Possible explanations for *non–H. pylori*, non-NSAID ulcers include gastric hypersecretion, gastric outlet obstruction, genetic predisposition, concomitant diseases (see Table 51-2), and heavy tobacco use. Treatment includes conventional ulcer healing therapies (see Table 51-9). Maintenance therapy may be required to prevent PUD complications since there is a high rate of recurrent bleeding within 1 year. No significant difference was seen in recurrent bleeding between famotide 40 mg daily and lansoprazole 30 mg daily for up to 24 monhts.[68]

Long-Term Maintenance of Ulcer Healing

Long-term maintenance of ulcer healing and the prevention of ulcer-related complications may be necessary in some patients. Because *H. pylori* eradication dramatically decreases ulcer recurrence, continuous maintenance therapy is primarily used to treat high-risk patients who failed *H. pylori* eradication, have a history of ulcer-related complications, have frequent recurrences of *H. pylori*–negative ulcers, and are heavy smokers or NSAID users. For most patients, standard maintenance dosages (see Table 51-9) are effective.

Treatment of Refractory Ulcers

Refractory peptic ulcers are ulcers that persist after 8 to 12 weeks of standard antisecretory drug treatment. Persistent *H. pylori* infection and use of NSAIDs are the most common causes of refractory ulcers. Additional contributing factors may include poor patient compliance, cigarette smoking, gastric acid hypersecretion, or tolerance to the antisecretory effects of an H2RA (see section "Antiulcer Agents" below). Patients with refractory ulcers should undergo upper endoscopy to confirm a nonhealing ulcer, exclude malignancy, and reassess *H. pylori* status with two or more diagnostic methods to increase sensitivity.[69] *H. pylori*–positive patients should receive eradication therapy (see "Treatment of *Helicobacter pylori*–Positive Ulcers" above). Fasting plasma gastrin levels can be checked if Zollinger-Ellison syndrome is suspected. Refractory ulcers, despite a complete standard PPI course, should be retreated with double-dose of PPI. Consideration can be given to using a different PPI.[69]

Antiulcer Agents

Proton Pump Inhibitors

PPIs (see Tables 51-9 and 51-11) dose-dependently inhibit basal and stimulated gastric acid secretion. The duration of acid suppression is a function of binding to the H^+/K^+-adenosine triphosphatase (ATPase) enzyme.[3] When PPI therapy is initiated, the degree of acid suppression increases over the first 3 to 4 days of therapy, as more proton pumps are inhibited. PPIs inhibit only those proton pumps that are actively secreting acid, thus they are most effective when taken 30 to 60 minutes before meals.[4] Symptomatic acid rebound on withdrawal of a PPI has been reported in healthy volunteers after 8 weeks of treatment.[70]

TABLE 51-11

PPI Formulations and Options for Administration

	Omeprazole	Esomeprazole	Lansoprazole	Pantoprazole	Rabeprazole	Dexlansoprazole
Commercially available oral formulations						
Capsule	X[a]	X	X			X[b]
Tablet	X[c]			X	X	
Oral disintegrating tablet			X			
Packet for oral suspension	X[d]	X[e]				
Extemporaneous oral preparations						
Pellets from capsule in water		X				
Pellets from capsule in applesauce	X		X			X
Pellets from capsule in juice	X	X[e]	X			
Extemporaneous preparation of delayed-release PPI in bicarbonate (omeprazole-sodium bicarbonate)	X		X	X		
Parenteral formulations						
IV	X (not available in the United States)	X		X		

PPI, proton pump inhibitor; X, product is available.

[a] Omeprazole is available as delayed-release enteric-coated pellets in a capsule or as immediate-release capsule that contains 20 or 40 mg of omeprazole with 1,100 mg sodium bicarbonate (equivalent to 304 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg capsules should not be substituted for the 40 mg immediate-release omeprazole-sodium bicarbonate capsule.

[b] Dexlansoprazole is available as a dual delayed-release formulation in capsules for oral administration. The capsule contains dexlansoprazole in a mixture of two types of enteric-coated granules with different pH-dependent dissolution profiles.

[c] Omeprazole oral tablets are available as 20 mg delayed-release nonprescription tablets.

[d] Omeprazole oral suspension is available as 20 or 40 mg omeprazole with 1,680 mg sodium bicarbonate (equivalent to 460 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg packets should not be substituted for the 40 mg immediate-release omeprazole-bicarbonate packet.

[e] No published information; based on omeprazole data.

PPIs are formulated as delayed-release enteric-coated dosage forms that have pH-sensitive granules contained in gelatin capsules (omeprazole, esomeprazole, prescription and nonprescription lansoprazole, and dexlansoprazole), rapidly disintegrating tablets (lansoprazole), and delayed-release enteric-coated tablets (rabeprazole, pantoprazole, and nonprescription omeprazole) (see Table 51-11). The pH-sensitive enteric coating prevents degradation and premature protonation of the drug in stomach allowing the drug to be dissolved then absorbed in the duodenum at a higher pH. Dexlansoprazole is formulated with a dual-release mechanism that provides inhibition of proton pumps that become activated after initial release of the medication while omeprazole is also available as an immediate-release formulation (oral suspension, oral capsule) containing sodium bicarbonate, which can control intragastric pH in the absence of food.[71] Parenteral formulations include omeprazole (not available in the United States), esomeprazole, and pantoprazole.

PPIs provide similar rates of ulcer healing, symptom relief, and maintenance of ulcer healing when used in recommended dosages (see Table 51-9).[3] Higher than indicated daily doses should be divided to obtain better 24-hour control of intragastric pH. Older adults and patients with renal impairment do not require dosage reductions, but dosage reductions should be considered in patients with severe hepatic disease.[72] Short-term adverse effects of PPIs are like those observed with the H2RAs (headache, nausea, and abdominal pain). Immediate-release formulations contain sodium bicarbonate, and thus are contraindicated for patients with metabolic alkalosis and hypokalemia.

Drug Interactions

Since PPIs increase intragastric pH, they may alter the bioavailability of orally administered drugs that are weak bases (eg, ketoconazole), digoxin, or pH-dependent dosage forms. This interaction is especially important with antiretroviral therapies for treatment of HIV and direct acting antivirals for hepatitis C, as reduced absorption can lead to therapeutic failure due to development of viral resistance.[73,74] Omeprazole and esomeprazole selectively inhibit the hepatic CYP2C19 pathway and may decrease the elimination of several drugs (eg, phenytoin, warfarin, diazepam, and carbamazepine).[51] PPIs may increase the metabolic clearance and decrease the GI absorption of levothyroxine resulting in increased thyroid-stimulating hormone levels and a corresponding increase in the levothyroxine dose.[75] Few drug-drug interactions (eg, phenytoin, warfarin, methotrexate) involving PPIs are clinically significant and constitute a major clinical risk.[51]

A controversial PPI drug interaction involves the antiplatelet drug clopidogrel. Clopidogrel is converted to its active form through CYP2C19. PPIs may attenuate the antiplatelet effect of clopidogrel by inhibiting or competing for this metabolic pathway. FDA safety guidelines recommend that the coadministration of omeprazole, omeprazole/sodium bicarbonate, or esomeprazole with clopidogrel be avoided because they reduce the effectiveness of clopidogrel. Warnings regarding omeprazole, esomeprazole, and other interacting drugs (eg, cimetidine) are contained in the clopidogrel package insert as well. This interaction is further complicated since genetic polymorphisms of the CYP2C19 gene leading to decreased biotransformation of clopidogrel to its active form may also explain reduced effectiveness of clopidogrel. Whether the use of other PPIs such as pantoprazole, lansoprazole, dexlansoprazole, and rabeprazole interacts with clopidogrel remains uncertain as the capacity to inhibit CYP2C19 varies among these PPIs.[76] Although pharmacodynamic studies suggest attenuated anti-platelet effects of clopidogrel with omeprazole, it does not appear to translate to increased cardiovascular risk in most studies. In randomized, double-blind, placebo-controlled studies of clopidogrel and omeprazole, there was no increased cardiovascular risk noted; however, the combination reduced the risk of upper GI bleeding.[77] Given the limitations of existing studies, administration of clopidogrel with PPIs should be balanced based upon cardiovascular and gastrointestinal risk.[76,78]

Potential Long-Term Safety Issues

Prolonged hypergastrinemia and chronic hypochlorhydria from long-term PPI use has been associated with numerous potential risks and safety issues (see Table 51-10).[79] Issues with study design, confounding, and subject selection make it difficult to attribute direct causality of PPIs for these potential safety issues. Patients receiving long-term PPIs can develop increases in serum gastrin levels, which exerts tropic effects on enterochromaffin-like cells. These cells have potential for inducing carcinoid tumors within the stomach during or after chronic acid suppression; however, there is very limited evidence (ie, case reports) of this effect, and a causal relationship between PPI use and gastric cancers has not yet been established.[2] There is also no evidence to support an association between PPIs and colonic polyps or colorectal cancer. Chronic PPI use is also associated with alterations of the intestinal microbiome, including small intestinal overgrowth and *C. difficile* infection because of inhibition of gastric acid and bacterial proton pumps. The full impact of changes in gastric and intestinal bacterial diversity and composition is unclear.[79,80]

Gastric acid is an important factor in nutrient absorption and protects against bacterial colonization of the stomach. Chronic acid suppression has been associated with increased risk of nutrient malabsorption and enteric infections. Acid suppression has been implicated as a risk factor for community-acquired pneumonia (CAP) and enteric infections (*C. difficile*, *Salmonella*, *Campylobacter*). There is a higher adjusted relative risk of CAP for patients using PPIs compared with controls, particularly in patients receiving higher doses or within the first 30 days of therapy.[79] The results of these retrospectively designed studies need to be interpreted cautiously because of the variability in the length of therapy for current PPI users and the inclusion of older (older than 60 years) patients with concomitant comorbidities. PPIs are linked with various enteric infections, but the most convincing data were with *C. difficile*. Sustained elevations in intragastric pH may facilitate the survival of *C. difficile* spores. However, the magnitude of risk varies and causality is difficult to establish. The risk of various infections associated with PPI therapy cannot be firmly established until the results of large prospective studies are made available.

The absorption of vitamin B_{12}, dietary iron, and calcium requires an acidic environment and may be adversely affected by long-term use of PPIs (see Table 51-12). The clinical importance of PPIs on absorption has not been established, and routine monitoring of B_{12} and iron levels cannot be routinely recommended. Adequate supplementation and monitoring should be considered in high-risk populations (eg, older patients, vegetarians, alcohol misuse) who may be already depleted. Hypomagnesemia, both symptomatic and asymptomatic, has been reported with PPI use with serious adverse events including tetany, arrhythmias, and seizures (see Table 51-12). In most cases it occurs in patients taking PPIs more than 1 year but can occur with as little as 3 months of therapy. High PPI dosage and long-term therapy have been associated with an increased risk of hip, wrist, and spine fractures related to reduction in calcium absorption. The FDA has revised the warnings and precautions of prescription and nonprescription PPIs to reflect these potential risks. Routine bone density tests for osteoporosis screening, calcium supplementation, or other precautions cannot be recommended solely based on chronic PPI therapy.[51]

TABLE 51-12

Drug Monitoring Table

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
PPIs	Headache, N/V/D, flatulence Less common: thrombocytopenia, neutropenia, hypomagnesemia, hypocalcemia, liver function abnormalities, renal impairment	Baseline and periodic CBC, serum electrolytes, renal/liver function	Well tolerated; may be associated with increased risk of fractures, pneumonia, *Clostridioides difficile* infection
H2RA	Headache, dizziness, diarrhea, somnolence, gynecomastia (cimetidine) Less common: thrombocytopenia, neutropenia, liver function abnormalities, renal impairment, pancreatitis	Baseline and periodic CBC, serum electrolytes, renal/liver function	
Sucralfate	Constipation, aluminum toxicity, gastric bezor		
Misoprostol	Diarrhea, abdominal pain, headache, nausea/vomiting, flatulence, dysmenorrhea, hypophosphatemia	Pregnancy test Serum phosphate	Avoid in pregnancy

CBC, complete blood count; H2RA, H_2-receptor antagonists; PPIs, proton pump inhibitors.

Data from References [4,11].

H2-Receptor Antagonists

Ulcer healing is comparable among H2RAs with equipotent multiple daily doses or a single full dose given after dinner or at bedtime (see Table 51-9), but tolerance to their antisecretory effect may occur. Twice-daily administration may be beneficial in patients with daytime ulcer pain while patients who smoke cigarettes may require higher doses or a longer duration of treatment. H2RAs are renally eliminated, thus a dosage reduction is recommended for patients with moderate-to-severe renal impairment. The short- and long-term safety of all H2RAs is similar. Thrombocytopenia is a common yet likely overestimated hematologic adverse effect that occurs with all H2RAs and is reversible (see Table 51-12). The H2RAs decrease acid secretion and may alter the bioavailability of orally administered drugs. Cimetidine inhibits several CYP450 isoenzymes, resulting in numerous drug interactions (eg, theophylline, lidocaine, phenytoin, warfarin, and clopidogrel). Famotidine and nizatidine do not interact with drugs metabolized by the hepatic CYP450 pathway. In April 2020, the Food and Drug Administration (FDA) recommended withdrawal of all ranitidine products from the US market following a report that, when stored at higher than recommended temperatures, products could contain unsafe quantities of N-nitrosodimethylamine (NDMA), a probable human carcinogen.[81]

Sucralfate

Sucralfate heals peptic ulcers but is not widely used today for this indication. Deterrents to its use include the requirement for multiple doses per day, large tablet size, and the need to separate the drug from meals and potentially interacting medications (eg, fluoroquinolones). Drug interactions can be minimized by giving the interacting drug at least 2 hours before sucralfate, or avoidance as with fluoroquinolones. Constipation may be troublesome especially in older individuals, and seizures have been observed in dialysis patients taking aluminum-containing antacids. Hypophosphatemia may develop with long-term treatment. Rarely, gastric bezoar formation has been reported (see Table 51-12).

Prostaglandins

The synthetic PGE_1 analogue, misoprostol, moderately inhibits acid secretion and enhances mucosal defense. Antisecretory effects are dose dependent over the range of 50 to 200 mcg, and cytoprotective effects occur in humans at doses of greater than 200 mcg. The most troublesome adverse effect is diarrhea which is dose-dependent; develops in 10% to 30% of patients; and is accompanied by abdominal cramping, nausea, flatulence, and headache.[3] Taking the drug with or after meals and at bedtime may minimize the diarrhea (see Table 51-12). Misoprostol is contraindicated in pregnant women because it produces uterine contractions that may endanger pregnancy. If misoprostol is prescribed to women in their childbearing years, contraceptive measures must be confirmed, and a negative serum pregnancy test should be documented within 2 weeks of initiating treatment (see Table 51-12).

Bismuth Preparations

Bismuth subsalicylate and bismuth subcitrate potassium are the only available bismuth salts in the United States. Possible ulcer healing mechanisms include an antibacterial effect, a local gastroprotective effect, and stimulation of endogenous PGs. Bismuth salts do not inhibit or neutralize acid. Bismuth subsalicylate is regarded as safe and has few adverse effects when taken in recommended dosages. Bismuth salts should be used with caution in older patients and in patients with renal failure as renal insufficiency may decrease bismuth elimination. Bismuth subsalicylate may cause salicylate sensitivity or bleeding disorders and should be used with caution for patients receiving concurrent salicylate therapy. Bismuth salts impart a black color to stool and possibly the tongue with liquid preparations. Long-term use of bismuth salts is not recommended due to the potential for bismuth toxicity.

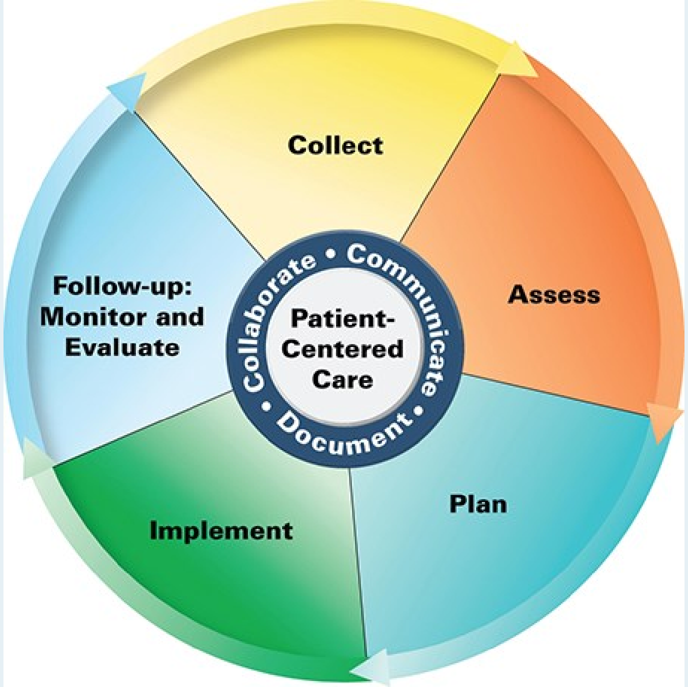
Antacids

Antacids neutralize gastric acid, inactivate pepsin, and bind bile salts. Aluminum-containing antacids also suppress *H. pylori* and enhance mucosal defense. The GI adverse effects are most common and are dose dependent: Aluminum-containing antacids cause constipation, and magnesium salts can cause an osmotic diarrhea. Aluminum-containing antacids (except aluminum phosphate) form insoluble salts with dietary phosphorus and interfere with phosphorus absorption. Hypophosphatemia occurs most often for patients with low dietary phosphate intake (eg, malnutrition or alcoholism). Combined treatment with sucralfate may amplify the hypophosphatemia and aluminum toxicity.

Magnesium excretion is impaired in patients with a creatinine clearance of less than 30 mL/min (0.5 mL/s) that may lead to toxicity; thus, magnesium-containing antacids should be avoided in these patients. Hypercalcemia may occur for patients with normal renal function taking more than 20 g/day of calcium carbonate and for patients with renal failure who are taking more than 4 g/day. The milk-alkali syndrome (ie, hypercalcemia, alkalosis, renal stones, increased blood urea nitrogen, and increased serum creatinine concentration) occurs with high calcium intake for patients with systemic alkalosis produced by either ingestion of absorbable antacids (sodium bicarbonate) or prolonged vomiting. Antacids may alter the absorption and excretion of drugs when administered concomitantly (eg, iron, warfarin, tetracycline, digoxin, quinidine, isoniazid, ketoconazole, or the fluoroquinolones). Most interactions can be avoided by separating the antacid from the oral drug by at least 2 hours.

PATIENT CARE PROCESS

Patient Care Process for Peptic Ulcer Disease (PUD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient medical history (personal and family) especially prior history of *H. pylori* infection, previous peptic ulcers, or previous upper GI disorders (see Table 51-4)
- Social history (eg, tobacco and ethanol use) as well as recent medical procedures and stress levels (see Table 51-2)
- Current medications, especially NSAIDS (nonprescription and prescription) use of nonprescription proton pump inhibitors (PPIs), other acid reflux treatments, anticoagulants, and antiplatelet medications. If prior NSAID use, note medication, dosage, and duration of use
- Pain: presence or absence, rating (1-10), quality, and location (see Table 51-5)
- Objective Data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Labs including hemoglobin (Hgb), hematocrit, assessment of kidney and liver function, gastric acid secretory studies, and stool hemoccult
    - Urea breath test (UBT) for detection of *H. pylori*. Follow-up culture with endoscopy recommended (see Table 51-6)

  - Imaging studies: Upper endoscopy

Assess

- Hemodynamic stability (eg, systolic BP >90 mm Hg, Hr >110 bpm, O_2 sat <90% [0.90])
- Presence of active gastric bleeding based on imaging studies
- Presence of GI-bleed provoking factors (low platelets, anticoagulant/antiplatelet use, NSAID use, age >65, recent surgery, severe co-morbidities, eg, cardiovascular disease) (see Table 51-4)
- Presence/absence of *H. pylori*
- Emotional status (eg, anxiety, depression, stress levels)
- Ability/willingness to pay for ulcer treatment options
- Ability/willingness to discontinue NSAIDS and switch to another pain reliever, if applicable
- Ability/willingness to obtain laboratory monitoring tests (eg, *H. pylori* status to confirm eradication) (see Table 51-7)
- Ability/willingness to follow a multiple drug regimen for 10 to 14 days, with some doses to be taken at specific times

Plan

- Drug therapy regimen based on ulcer classification and patient's antibiotic tolerance (eg, penicillin allergy) (see)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug-specific information, medication administration)
- Self-monitoring for resolution of symptoms such as epigastric pain, dyspepsia, when to seek emergency medical attention

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (endoscopic *H. pylori* culture, lab tests: CBC, serum electrolytes, renal/liver function; see Table 51-12)

Follow-Up: Monitor and Evaluate

- Resolution of PUD symptoms such as epigastric pain and dyspepsia
- Presence of adverse effects (eg, N/V/D [PPIs, H2RAs, metronidazole, other antibiotics]), headaches (PPIs and H2RAs)
- Patient adherence to treatment plan using multiple sources of information
- Monitor patient for symptoms of PUD recurrence, especially if their risk factors change

**Collaborate with patient, caregivers, and other healthcare professionals.*

EVALUATION OF THERAPEUTIC OUTCOMES

6 Table 51-13 lists the recommendations for treating and monitoring patients with PUD. Relief of epigastric pain should be monitored throughout the course of treatment for patients with either *H. pylori*– or NSAID-related ulcers. Ulcer pain typically resolves in a few days when NSAIDs are discontinued and within 7 days upon initiation of antiulcer therapy. Patients with uncomplicated PUD are usually symptom free after treatment with

any of the recommended antiulcer regimens. Persistent or recurrent symptoms within 14 days following treatment completion suggests failure of ulcer healing or *H. pylori* eradication or presence of an alternate diagnosis such as GERD. Eradication should be confirmed after treatment in all patients, particularly among individuals who are at risk for complications (eg, prior bleeding ulcer). The UBT and fecal antigen are the preferred methods to confirm *H. pylori* eradication when endoscopy is not indicated. Medication adherence should be assessed for patients who fail therapy. Many at-risk patients treated with NSAIDs do not receive adequate prophylaxis for GI complications; however, therapeutic outcomes can be improved by advocating preventive strategies. Any signs or symptoms of bleeding, obstruction, penetration, or perforation require prompt investigation to avoid complications. A follow-up endoscopy is justified for patients with frequent symptomatic recurrence, refractory disease, complications, or suspected hypersecretory states.

TABLE 51-13

Recommendations for Treating and Monitoring Patients with *Helicobacter Pylori*–Associated and NSAID-Induced Ulcers

***H. pylori*–associated ulcer**

1. Recommend drug treatment as presented in the chapter text. See Tables 50–7 and 50–8
2. Assess patient allergies to determine if allergic to penicillin (or other antibiotics) so that drug regimens that contain penicillin (or other antibiotics) can be avoided. Avoid regimens that contain tetracycline in children
3. Assess patient use of alcohol or alcohol-containing products with metronidazole and oral birth control medications with antibiotics and counsel appropriately
4. Assess likelihood of nonadherence to the drug regimen as a cause of treatment failure
5. Recommend a different antibiotic combination if *H. pylori* eradication fails and a second treatment is planned
6. Inform the patient of change in stool color when bismuth salicylate is included in an *H. pylori* eradication regimen
7. Assess and monitor patients for potential adverse effects, especially those associated with metronidazole, clarithromycin, and amoxicillin
8. Assess and monitor patients for potential drug interactions, especially those receiving metronidazole, clarithromycin, or cimetidine
9. Monitor patients for salicylate toxicity, especially patients receiving co-therapy with other salicylates and anticoagulants and patients with renal insufficiency
10. Monitor patients for persistent or recurrent symptoms within 14 days after completion of a course of *H. pylori* eradication therapy
11. Provide education to patients who are receiving *H. pylori* eradication therapy and include why antibiotic and antiulcer combinations are used; when and how to take medications; adverse effects; alarm symptoms; the importance of adherence to the entire course of drug treatment; and contact their healthcare provider if alarm symptoms develop (eg, blood in the stools, black tarry stools, vomiting, severe abdominal pain), or if symptoms persist or return after *H. pylori* eradication

NSAID-induced ulcer

1. Recommend drug treatment as presented in the chapter text
2. Assess risk factors for NSAID-induced ulcers and ulcer-related complications and recommend appropriate strategies for reducing ulcer risk (see Table 51-14)
3. Weigh patient risk factors for NSAID-related GI bleeding and cardiovascular events when selecting a strategy to reduce ulcer risk
4. Recommend eradication treatment for *H. pylori*–positive patients taking NSAIDs
5. Monitor patients for signs and symptoms of NSAID-related upper GI complications
6. Assess and monitor patients for potential drug interactions and adverse effects (especially misoprostol)
7. Provide patient education to patients who are at risk of NSAID-induced ulcers or GI-related complications and include why co-therapy is used with nonselective NSAIDs, when and how to take medications, adverse effects, alarm symptoms, when to contact their healthcare provider, and the importance of adherence to drug treatment

TABLE 51-14

Prevention of Peptic Ulcer Disease in Patients Receiving Chronic NSAID Therapy

	Low Gastrointestinal Risk[a]	High Gastrointestinal Risk[b,c]
Low Cardiovascular Risk	Nonselective NSAIDs	Nonselective NSAIDs plus PPI; celecoxib plus PPI[d]
High Cardiovascular Risk[e]	Naproxen; add PPI if patient is taking aspirin	No NSAIDs; naproxen plus PPI; low-dose celecoxib plus aspirin plus PPI may be an alternative option[f]

[a] No risk factors.

[b] Presence of risk factors (patients 60 years or older, history of peptic ulcers, receiving concomitant antiplatelet agents, anticoagulants, corticosteroids, or selective serotonin reuptake inhibitors).

[c] In patients with prior history of ulcers, adopt test-and-treat strategy to exclude *H. pylori* infection.

[d] Consider when patients have complicated ulcer history or presence of multiple risk factors.

[e] Use risk calculator (eg, Framingham or atherosclerotic cardiovascular disease (ASCVD) risk calculators) to estimate cardiovascular risk on the basis of several variables. Patients with a history of cardiovascular events or diabetes are considered high cardiovascular risk.

[f] NSAIDs with increasing selectivity for Cyclooxygenase-2 (COX-2) (ie, celecoxib) have been associated with increased cardiovascular risk, and this risk appears to be increased in patients with established cardiovascular disease. Patients with cardiovascular disease or risk factors, recommendations for pain management (in the order listed) include: acetaminophen, aspirin, tramadol, opioids (short-term), nonacetylated salicylates (eg, diflunisal), NSAIDs with low COX-2 selectivity (eg, naproxen), NSAIDs with some COX-2 selectivity (eg, nabumetone), and COX-2 selective agents (ie, celecoxib).

NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

Data from Reference 4.

RELATED DISORDERS

Upper Gastrointestinal Bleeding

Upper GI bleeding is one of the most common GI emergencies with more than 200,000 hospital admissions annually.[6] There are about 48 to 160 cases of upper GI bleeding per 100,000 adults annually in the United States, and the in-hospital mortality rate associated with acute hemorrhage remains relatively high at 2% despite a decreased incidence of PUD and improvements in the management of upper GI bleeding.[6] Upper GI bleeding is categorized as variceal or nonvariceal bleeding. A complete discussion of variceal bleeding is found elsewhere (Chapter 55). Two common types of nonvariceal bleeding are bleeding from chronic peptic ulcers, often related to antithrombotic therapy, and bleeding from SRMD.[82] Upper GI bleeding associated with chronic PUD usually precedes hospital admission. Bleeding associated with SRMD develops in critically ill patients during hospitalization.[83,84] The underlying pathophysiology of bleeding from a peptic ulcer or from SRMD is similar in that impaired mucosal defense in the presence of gastric acid and pepsin leads to mucosal damage. In chronic PUD, *H. pylori* infection and NSAID use are the most important etiologic factors. The primary pathogenic factor of SRMD in critically ill patients is thought to be mucosal ischemia, which is a result of reduced gastric blood flow resulting from splanchnic hypoperfusion.[83,84] Stress-related mucosal lesions are characteristically asymptomatic, numerous, located in the proximal stomach, and unlikely to perforate. Bleeding from SRMD occurs from superficial mucosal capillaries, whereas bleeding associated with chronic PUD usually results from a single vessel.[83,84] The mortality rate associated with clinically important stress-related mucosal bleeding (SRMB) is approximately 50% and is related to disease severity and comorbidities in this patient population. The mortality associated with chronic PUD-related bleeding is approximately 5% but can increase dramatically in select patient populations.[83,84] Initial management of acute upper GI bleeding focuses on aggressive resuscitation and hemodynamic stability.

Peptic Ulcer–Related Bleeding

Clinical Presentation and Diagnosis

Hematemesis (vomiting up blood), melena (dark, tarry stools), or both are the most common presenting signs and symptoms of PUD-related bleeding. Risk for adverse outcomes must be rapidly assessed to determine if the patient's condition constitutes a medical emergency.[84] Two risk stratification tools exist for early assessment and triage. The Blatchford score is used to evaluate the need for urgent endoscopic intervention for patients presenting with PUD-related bleeding. The scale values range from 0 to 23, with higher scores indicating higher risk. The Rockall Score is composed of two assessments: the clinical score, which is performed prior to endoscopy, and the endoscopic score. The use of these risk stratification tools can reduce the requirement of endoscopic procedures and lead to early discharge for low-risk patients while ensuring rapid intervention for patients at higher risk.[84] When considering the risk of death due to PUD bleeding, the following patients generally have poorer prognoses and usually require more aggressive intervention including admission to an intensive care unit (ICU): older age (> 60 years), hypotension (SBP <100 mm Hg), tachycardia (HR < 100 BPM), shock, poor overall health, comorbid conditions, low initial hemoglobin/hematocrit, active bleeding (red blood per rectum or hematemesis), sepsis, and elevated serum creatinine or serum transaminases.[85] Diagnostic endoscopy is usually performed within 24 hours of presentation to identify the source of the bleeding, assess the potential risk for rebleeding using the Forrest classification of lesions, and, if appropriate, employ therapeutic interventions to promote hemostasis.[85,86]

The appearance of the ulcer at the time of endoscopy is a prognostic indicator for the risk of rebleeding. Clean-based (Forrest type III) and flat spot (pigmented; Forrest type IIc) ulcers are most commonly seen and are associated with a low risk of rebleeding (5% and 10%, respectively). In most cases, patients with clean-based ulcers can be treated as an outpatient on antiulcer therapy, while patients with flat spot ulcers may be admitted to the general hospital ward for brief observation.[84] Patients with an adherent clot overlying the ulcer base (Forrest type IIb) are at intermediate risk of rebleeding (22%-33%), and controversy exists as to the appropriate management of these patients. Patients with a visible vessel (Forrest type IIa) or active bleeding (Forrest type Ia or Ib) are at the highest risk of rebleeding (43%-50% and 55%-90%, respectively) and should receive ICU care for at least 24 hours followed by monitoring on a general medical/surgical service for an additional 48 hours as rebleeding significantly increases mortality.[84]

Treatment

Initial therapy for patients with defined hemostatic instability should focus on correcting fluid volume loss through appropriate volume resuscitative measures. This is usually accomplished with a continuous 0.9% sodium chloride infusion or blood products if clinically indicated.[82] The use of nasogastric (NG) tubes as an aid in early assessment remains controversial, but nasogastric lavage has no impact on transfusion requirements, surgery, or mortality.[82,84] Several endoscopic treatment approaches (eg, thermocoagulation, argon plasma coagulation therapy, injection sclerotherapy, hemostatic clips, and ligation) can be used.[35]

Antisecretory agents are often used as adjuvant therapy to endoscopic procedures to prevent PUD rebleeding in high-risk patients because acid impairs clot stability. PPIs reduce the incidence of rebleeding and need for surgery but have no significant impact on overall mortality.[84] There is no difference in recurrent bleeding, need for surgery, or mortality when comparing equivalent dosing of oral and intravenous PPI therapy.[88] Oral or intermittent IV dosing of PPIs (at cumulative daily omeprazole doses of 80-160 mg) may be preferred over continuous fusion (eg, omeprazole 8 mg/hr) in order to provide a greater ease of administration. PPI therapy is not a replacement for interventional endoscopy in patients with a high risk of rebleeding, as data demonstrate that the combination of a PPI with therapeutic endoscopy is superior to either strategy alone. The risk of rebleeding is greatest within the first 72 hours, and thus antisecretory therapy to prevent rebleeding in high-risk patients should be employed in this time frame. Patients with high-risk endoscopic lesions should be transitioned to twice-daily PPI for 14 days. Patients with low-risk endoscopic lesions can be treated with once-daily PPI. Once-daily PPI treatment should be continued for 4 to 8 weeks in all patients with peptic ulcer bleeding.[84]

Patients with upper GI bleeding should be tested for *H. pylori* at the time of endoscopy (see section "Tests for *Helicobacter pylori*" above). However, the tests are associated with an increased rate of false-negatives when obtained during acute bleeding episodes. If the initial results of the rapid urease test and/or histology are negative, a confirmatory test should be performed following the acute bleeding episode. Ulcer treatment, including *H. pylori* eradication, should be initiated after the acute bleeding episode has resolved (see "Treatment of *H. Pylori*–Positive Ulcers" and "Treatment of NSAID-

Induced Ulcers" above).

Stress-Related Mucosal Bleeding

Epidemiology and Risk Factors

Clinically important bleeding increases ICU length of stay, results in excessive healthcare costs, and is associated with increased mortality. Thus, attempts to prevent SRMB are warranted in high-risk patients. Prophylactic therapy to prevent bleeding is most effective if initiated early in the patient's course.[83] The majority (75%-100%) of critically ill patients develop SRMD within the first 1 to 3 days of admission to an ICU, but the incidence of clinically important SRMB (defined as overt bleeding with concomitant hemodynamic instability and likely requirement for blood products) has decreased to is 2% to 5%.[83]

Patients who are at risk for SRMB include those with respiratory failure (ie, need for mechanical ventilation for longer than 48 hours), coagulopathy (ie, INR greater than 1.5, platelet count less than 50,000/mm^3 [50×10^9/L]), hypotension, sepsis, hepatic failure, acute renal failure, high-dose corticosteroid therapy (ie, more than 250 mg/day hydrocortisone or equivalent), multiple trauma, severe burns (ie, more than 35% of body surface area), head injury, traumatic spinal cord injury, major surgery, prolonged ICU admission (ie, more than 7 days), or history of GI bleeding. The relative importance of the various risk factors remains controversial, but most clinicians concur that patients with respiratory failure or coagulopathy should receive prophylaxis, as these two factors are independent risk factors for SRMB.[89]

Prevention and Treatment

Prevention of SRMB includes resuscitative measures that restore mucosal blood flow, and pharmacotherapy that either maintains an intragastric pH of greater than 4 or provides gastric mucosal protection.[83,90] Although the benefits of enteral nutrition to patient outcome (eg, improved nutritional status enhances mucosal integrity) are of overall critical importance, its precise role as a sole modality to prevent SRMB remains controversial. Patients receiving enteral nutrition may not require medications for SRMB prophylaxis, and such therapies may increase the risk of adverse complications, particularly nosocomial pneumonia, over enteral nutrition alone.[91,92] Therapeutic options for the prevention of SRMB include antisecretory drugs (H**2**RAs and PPIs), and sucralfate.[83,89]

Sucralfate is an option for SRMB but requires multiple daily dosage administration (up to four times daily). Also, it may occlude nasogastric (NG) tubes, and possibly cause adverse effects previously discussed. Although sucralfate may have a lower risk of pneumonia compared to antisecretory therapy, these factors limit its use for SRMB prophylaxis. PPIs have become the most widely used therapy since they are more potent in inhibiting acid secretion and, unlike H2RAs, tolerance does not develop. Improved efficacy for SRMB when the PPIs are used as prophylaxis must be balanced against adverse events including increased risk of enteric infections, namely *C. difficile*–associated diarrhea and evidence-based nosocomial pneumonia, which are associated with increased healthcare costs.[89,93] A decision analytic model determined H2RA stress ulcer prophylaxis reduced costs, increased survival, and avoided complications compared with PPI therapy.[94] There are several evidence-based dosing regimens for SRMB prophylaxis (see Table 51-15).[83]

TABLE 51-15

Pharmacotherapy Options for Prophylaxis of Stress-Related Mucosal Bleeding

Drug and Route	Dosage
Parenteral H2RAs	
Cimetidine	300 mg IV loading dose followed by 50 mg/hr as a continuous infusion[a] or 300 mg IV every 6-8 hours
Ranitidineb	6.25 mg/hr as a continuous infusion or 50 mg IV every 6-8 hours
Famotidine	1.7 mg/hr as a continuous infusion or 20 mg IV every 12 hours
Oral/NG Tube PPIs	
Omeprazole	20-40 mg orally/NG tube[c] every 12-24 hours
Omeprazole/bicarbonate powder for oral suspension	40 mg orally/NG tube to start, then followed by an additional 40 mg in 6-8 hours as a loading dose, and then 40 mg every 24 hours
Lansoprazole	30 mg orally/NG tube[c,d] every 12-24 hours
Pantoprazole	40 mg orally/NG tube[c] every 12-24 hours
Parenteral PPIs	
Pantoprazole	40-80 mg IV every 12-24 hours
Esomeprazole	40 mg IV every 12-24 hours

[a] Product is FDA approved for the prevention of stress-related mucosal bleeding.

[b] All ranitidine products were removed from the US market effective April 2020.

[c] Administered as an extemporaneously compounded suspension made with sodium bicarbonate.

[d] Administered as a rapidly disintegrating tablet given orally or by NG tube dissolved in 10 mL of water.

H2RA, histamine-2 receptor antagonist; NG, nasogastric; PPI, proton pump inhibitor.

Even though PPIs have become the most widely used prevention therapy, numerous studies and years of experience support the use of H2RAs, and they remain a recommended option for the prevention of SRMB.[83] Parenteral H2RAs may be administered as either continuous infusions or intermittent bolus doses (see Table 51-15). Cimetidine, given as a continuous IV infusion, is the only FDA-labeled H2RA for the prevention of SRMB. Drug interactions are more common with cimetidine, thus the other H2RAs (famotidine, ranitidine) have been used more frequently.[83] Adverse events associated with the use of H2RAs for the critically ill patient include thrombocytopenia, mental status changes (more common in older patients or individuals with renal or hepatic compromise), and tachyphylaxis (especially with parenteral or high-dose therapy). Given that the H2RAs are renally eliminated, dosage reductions are recommended for patients with renal dysfunction.

When deciding on the most appropriate pharmacotherapy plan for the prevention of SRMB for a specific patient, the clinical presentation, risk factors, and medication costs should be used as a guide. Oral H2RA or PPI suspension is safe and cost-effective for patients who can take oral medication or have a working NG tube in place. For patients who are not able to utilize one of these routes, parenteral antisecretory therapies are appropriate. However, if the patient has any relative or absolute contraindications to an H2RA, then an IV PPI may be the most appropriate prophylaxis option.

Improvement in the patient's overall medical condition (resolution of risk factors, discharge from the ICU, extubation, and oral intake) suggests that prophylactic therapy can be discontinued. Often patients are continued on SRMB prophylaxis on transition to the general medical/surgical unit and frequently discharged on oral PPI therapy without an appropriate indication. This results in unnecessary costs for the patient and the healthcare system.[89] Patients in whom SRMB prophylaxis is no longer indicated should be identified. If a patient develops clinically important bleeding, endoscopic evaluation of the GI tract is indicated along with aggressive antisecretory therapy (see section "Peptic Ulcer–Related Bleeding" above).

Zollinger-Ellison Syndrome

ZES, characterized by hypersecretion of gastric acid and severe gastroesophageal PUD, is caused by a neuroendocrine tumor (gastrinoma) that is present in the duodenum or pancreas. Gastrinoma has a yearly incidence of approximately 0.1 to three cases per million in the United States with ZES being the underlying cause of PUD in 0.1% to 1% of patients. ZES occurs spontaneously in 75% to 80% of patients, but 25% to 30% of patients have the familial form associated with multiple endocrine neoplasia type 1 (MEN1), an autosomal-dominant syndrome due to a variant in the *MEN1* gene. Patients with MEN1 commonly develop hyperparathyroidism, pituitary adenomas, and neuroendocrine tumors. Half (50%) of patients with MEN1 have ZES making gastrinoma and ZES the most common functional neuroendocrine tumor and syndrome in MEN1. Gastrinomas are usually slow growing, but approximately 60% to 90% are malignant with metastases to regional lymph nodes, liver, and other distant sites at time of diagnosis.[95]

Pathophysiology

Gastrinomas are derived from the enteroendocrine cells, form tumors mainly in the pancreas and proximal small intestine, and are generally classified under the larger term of neuroendocrine tumors. Most gastrinomas arise in the duodenum. Gastrinomas located in the pancreas carry a greater malignant potential. ZES pathophysiology is related to the trophic action of gastrin on parietal cells of the gastric antrum and the resulting hypersecretion of gastric acid. Most patients consequently develop large peptic ulcers frequently in the distal duodenum and even proximal jejunum, which is an uncommon location for ulcers resulting from *H. pylori* or the use of NSAIDs.[95]

Clinical Presentation and Diagnosis

Historically, patients with ZES presented with refractory PUD or complications of acid hypersecretion (perforation, penetration, bleeding, and esophageal stricture). Due to the widespread use of PPIs and H2RAs, this form of presentation has decreased drastically.[95] Patients commonly present with severe refractory heartburn, epigastric pain, and profound diarrhea. Diarrhea may be the only symptom in 10% to 20% of patients and is due to the osmotic load of high gastric acid, inhibition of sodium and water reabsorption by the intestinal brush border of high gastric acid secretion, and a malabsorptive component from inactivation of pancreatic digestive enzymes by gastric acid.[95]

ZES diagnosis is established when the serum gastrin is greater than 1,000 pg/mL (ng/L; 481 pmol/L) and the basal acid output (BAO) is more than or equal to 15 mEq/hr (mmol/hr) for patients with an intact stomach (BAO more than or equal to 5 mEq/hr [mmol/hr] for patients with previous gastric surgery) or when hypergastrinemia is associated with a gastric pH value of more than or equal to 2.[95] In situations in which the serum gastrin is between 100 and 1,000 pg/mL (ng/L; 48 and 481 pmol/L) and gastric pH is less than or equal to 2, a secretin or calcium proactive test is used to aid the diagnosis.[95] Identification of the location of the tumor with imaging techniques is essential, as early surgical resection prior to liver metastases is often curative.[96] The widespread use of PPIs, although effective in reducing symptoms, may mask the clinical presentation and PPI-related hypergastrinemia may further complicate the diagnosis.

TREATMENT

With the development of H2RAs and PPIs, medical management of ZES is feasible in almost all patients. Because of their long duration of action and potency, PPIs are now the drugs of choice for treating gastric acid hypersecretion in patients with ZES.[95] Many of the PPIs (omeprazole, esomeprazole, lansoprazole, esomeprazole, rabeprazole, and pantoprazole) are effective in ZES. Initial doses of 80 mg/day of pantoprazole (or an equivalent dose of other available PPIs) given every 8 to 12 hours is most effective at controlling gastric acid hypersecretion and reliving symptoms. IV PPIs can be used for those patients who do not tolerate oral therapy. PPIs must be dose adjusted in patients with ZES to normalize BAO levels to less than 15 mEq/hr (mmol/hr) or less than 5 mEq/hr (mmol/hr) in patients with reflux esophagitis or prior operations to reduce acid secretion, such as subtotal gastrectomy. PPI therapy can be gradually decreased after adequate control of hypersecretion is achieved.[95] Since 60% to 90% of gastrinomas are malignant, management of advanced disease may include surgical resection of primary and metastatic gastrinomas. Nonsurgical therapy may include treatment with chemotherapy, somatostatin analogues such as octreotide, interferon, and targeted-molecular therapies such as a mTor inhibitor (everolimus) or a tyrosine-kinase inhibitor (sunitinib).[95]

ABBREVIATIONS

ATPase	adenosine triphosphatase
BAO	basal acid output
CAP	community-acquired pneumonia
CLASS	Celecoxib Long-Term Arthritis Safety Study
COX	cyclooxygenase
COX-1	cyclooxygenase-1
COX-2	cyclooxygenase-2
CYP450	cytochrome P450
ECL	enterochromaffin-like
GERD	gastroesophageal reflux disease
H2RA	histamine-2 receptor antagonist
ICU	intensive care unit
IL	interleukin
INR	international normalized ratio
MALT	mucosa-associated lymphoid tissue
MAO	maximal acid output
MEN 1	multiple endocrine neoplasia type 1
NG	nasogastric
NSAID	nonsteroidal anti-inflammatory drug
NUD	nonulcer dyspepsia
PG	prostaglandin
PPI	proton pump inhibitor
PUD	peptic ulcer disease

SRMB	stress-related mucosal bleeding
SRMD	stress-related mucosal damage
TNF-α	tumor necrosis factor-α
UBT	urea breath test
ZES	Zollinger-Ellison syndrome

SELF-ASSESSMENT QUESTIONS

1. Nonsteroidal anti-inflammatory drug (NSAID)–induced ulcers differ from *Helicobacter pylori*–associated ulcers in that an NSAID-induced ulcer is most likely:

   A. Located in the stomach

B. Associated with less severe upper gastrointestinal (GI) bleeding

C. Associated with a greater degree of ulcer-related epigastric pain

D. Associated with gastric acid hypersecretion

2. Which of the following best describes the presentation of patients with *H. pylori*–induced ulcers?

A. Deep ulcer depth

B. A duodenal ulcer

C. Epigastric pain

D. Damage to the gastric mucosa

3. A 30-year-old woman with a medical history of rheumatoid arthritis is *H. pylori*–negative but undergoes endoscopy revealing an NSAID-induced ulcer. Assuming she must continue the NSAID following a brief interruption, which is the preferred medication for ulcer healing and prevention of future ulcers?

A. Misoprostol

B. Pantoprazole

C. Famotidine

D. Sucralfate

4. A 53-year-old white man with no known drug allergies presents to his primary care physician with a 2-week history of epigastric pain. He has no recent history of NSAID use, but completed a course of azithromycin for community acquired pneumonia 3 weeks ago. A serum antibody for *H. pylori* is obtained and is positive. Which of the following 14-day regimens would be considered the preferred initial therapy for *H. pylori*?

A. Proton pump inhibitor (PPI) + metronidazole + amoxicillin

B. PPI + metronidazole + clarithromycin

C. PPI + amoxicillin + clarithromycin

D. PPI + metronidazole + bismuth + tetracycline

5. Which of the following is an endoscopic test used to diagnose *H. pylori*?

A. Urea breath test

B. Mucosal biopsy

C. Fecal antigen

D. Antibody detection

6. You receive a phone call from a distressed patient who is concerned that her tongue has turned black after starting new medications for peptic ulcer disease (PUD). Which medication is causing the side effect?

A. Amoxicillin

B. Bismuth subsalicylate

C. Clarithromycin

D. Metronidazole

7. What is the recommended number of days for treatment of *H. pylori* when clarithromycin-based triple therapy is used?

   A. 5

   B. 7

   C. 14

   D. 21

8. A medical resident seeks your advice on an NSAID regimen for a 45-year-old woman with rheumatoid arthritis and major depressive disorder. She has no prior ulcer disease, no other medical conditions, and takes only sertraline 50 mg daily. Which of the following regimens should be used for prevention of NSAID-induced ulcers in this patient?

   A. Ibuprofen

   B. Naproxen

   C. Celecoxib

   D. Naproxen plus PPI

9. Chronic PUD-related bleeding differs from stress-related mucosal bleeding (SRMB) in that chronic PUD-related bleeding:

   A. Occurs due to mucosal ischemia from decreased gastric blood flow

   B. Usually occurs from a single vessel

   C. Requires aggressive resuscitation as initial management

   D. Results in a mortality rate of 50%

10. A 48-year-old patient was admitted to the medical ICU 48 hours ago with acute respiratory failure requiring subsequent intubation. They are currently receiving mechanical ventilation, has no renal insufficiency, and do not have a working NG tube. What is the best option for stress related mucosal bleeding (SRMB) prophylaxis for this patient?

    A. Pantoprazole 40 mg by mouth daily

    B. Famotidine 20 mg IV twice daily

    C. Sucralfate 1 g by mouth four times daily

    D. Pantoprazole 40 mg IV every 8 hours

11. Which of the following is true about Zollinger-Ellison syndrome (ZES)?

    A. ZES is the underlying cause of PUD in 1% to 10% of patients.

    B. A minority of patients develop large peptic ulcers in the distal duodenum.

    C. Gastrectomy is the only effective treatment of controlling gastric acid hypersecretion.

    D. Antisecretory therapy with PPIs is an effective means of medically managing ZES.

12. A medical student recently heard about a new “hybrid” treatment regimen for *H. pylori* eradication and requests a literature search on this topic.

Which of the following best represents a “hybrid” regimen?

A. Omeprazole, clarithromycin, and amoxicillin taken together for 14 days.

B. Famotidine, bismuth, tetracycline, and metronidazole taken together for 10 days.

C. Pantoprazole and amoxicillin taken together on days 1 to 5, followed by pantoprazole, clarithromycin, and metronidazole on days 6 to 10.

D. Rabeprazole and amoxicillin together for days 1 to 14, along with clarithromycin and metronidazole on days 7 to 14.

13. A 52-year-old female returns to clinic 4 weeks after completing a course of esomeprazole, clarithromycin, and amoxicillin for 10 days for an endoscopically confirmed duodenal ulcer. A fecal antigen test is positive. Which of the following represents the best course of action?

A. Do nothing.

B. Repeat a course of esomeprazole, clarithromycin, and amoxicillin but increase duration to 14 days.

C. Initiate omeprazole, bismuth subcitrate, metronidazole, and tetracycline for 10 days.

D. Initiate rabeprazole, clarithromycin, amoxicillin, and metronidazole for 10 days.

14. A 59-year-old man with hypertension, hyperlipidemia, myocardial infarction (4 years ago), arthritis and history of PUD presents to clinic complaining of worsening bilateral knee pain. His medications include lisinopril 20 mg daily, atorvastatin 80 mg at bedtime, enteric coated aspirin 81 mg daily, ibuprofen 600 mg three times daily, and metoprolol 100 mg twice daily. In addition to stopping ibuprofen, which of the following would you recommend for treatment of his chronic knee pain?

A. Initiate celecoxib 100 mg daily

B. Initiate naproxen 550 mg twice daily

C. Initiate naproxen 550 mg twice daily plus famotidine 20 mg twice daily

D. Initiate celecoxib 100 mg daily plus pantoprazole 40 mg daily

15. A 61-year-old female is diagnosed with Zollinger-Ellison syndrome. Which of the following represents an evidence-based initial treatment?

A. Famotidine 40 mg twice daily

B. Rabeprazole 40 mg twice daily

C. Omeprazole 20 mg twice daily

D. Misoprostol 400 mg twice daily

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Characteristics of NSAID-induced ulcers include preferential damage to gastric mucosa, deeper ulcers, involvement of a single blood vessel, and more severe bleeding.

2. **B.** *H. pylori*–related ulcers occur more commonly in the duodenum, have a superficial ulcer depth, and are less likely to have significant GI bleeding when compared to NSAID-induced ulcers.

3. **B.** PPIs are more effective at ulcer healing and prevention compared with H2RA and sucralfate. Misoprostol is also an effective agent for prevention of ulcers but would not be effective for ulcer healing. Since this woman is of childbearing age, use of misoprostol would require confirmation of negative pregnancy test and additional counseling.

4. **D.** Bismuth quadruple therapy would be the best option for this patient. In general, clarithromycin-based triple therapy is no longer recommended as a first-line option in the United States. In this scenario, regimens containing clarithromycin should be avoided given the patient's recent macrolide exposure. Triple therapy with PPI, amoxicillin, and metronidazole is less effective than triple therapy regimens containing clarithromycin.

5. **B.** Mucosal biopsy is an invasive test requiring endoscopy. Fecal antigen, serology, and urea breath test are noninvasive tests used in the diagnosis of *H. pylori*.

6. **B.** Bismuth preparations may cause nausea and a black tongue and/or stool.

7. **C.** Clarithromycin-based triple therapy is no longer recommended as a first-line therapy due to increased resistance, but when it is used, the duration should be 14 days to maximize the efficacy.

8. **D.** This patient has no CV history, but is considered high risk for PUD due to treatment with SSRI. SSRIs increase the risk of PUD and GI bleeding by sixfold. Ulcer prevention with a PPI is recommended along with either a nonselective NSAID or celecoxib.

9. **B.** Chronic PUD-related bleeding usually affects a single vessel and occurs slowly over time. However, SRMB is an acute condition with superficial ulcers, mainly affecting small capillaries, due to mucosal ischemia. Clinically significant bleeding due to SRMB is not common, but requires fluid resuscitation and has a high mortality rate.

10. **B.** The patient is receiving mechanical ventilation, so SRMB prophylaxis is indicated. Of the available choices, parenteral H2RA would be the best choice. A working nasogastric tube or feeding tube is needed for administration of oral dose forms. Intravenous PPIs at total daily doses equivalent to omeprazole 80-160 mg/day are only indicated for acute upper gastrointestinal bleeding.

11. **A.** ZES is a rare cause of PUD with an estimated incidence of 0.1% to 1% of all PUD cases. Ulcers usually form in the distal duodenum or proximal jejunum, which is a unique feature of ZES. Surgery and medical management with high-dose PPIs are both management strategies used for ZES.

12. **D.** Sequential therapy is a form of eradication therapy in which the antibiotics are administered in a sequence rather than together (Answer C). Non-bismuth quadruple therapy, also called "concomitant" therapy, is a regimen with a PPI, amoxicillin, clarithromycin, and metronidazole taken together at standard doses for 10 to 14 days. Hybrid therapy combines the strategies of concomitant and sequential therapy. Patients take 7 days of dual therapy (PPI and amoxicillin) followed by 7 days of quadruple therapy (PPI, amoxicillin, clarithromycin, and metronidazole).

13. C Patient has not eradicated *H. pylori* for a endoscopically confirmed duodenal ulcer, and the risk of ulcer recurrence is high. The patient has recent macrolide exposure, so regimens including clarithromycin should be avoided.

14. D Given the patient's prior ulcer history, ulcer prevention with a PPI is needed. Although some of the gastroprotective effect is lost in patients taking low-dose aspirin, it represents the best choice in this scenario. Since the patient is high-risk for cardiovascular disease, the lowest dose of celecoxib should be used.

15. **B.** ZES is a hypersecretory condition requiring high doses of proton pump inhibitors to reduce gastric acid. Any PPI can be used in doses equivalent to pantoprazole 80 mg given every 8 to 12 hours. The equivalent dosing of rabeprazole is 50% of the pantoprazole dose (see Table 51-9). Omeprazole would be a good choice, but the dose in this scenario is subtherapeutic for ZES. H2RA are less effective overall and the doses used would need to be considerably higher. Misoprostol is not indicated for ZES.

Chapter 52: Inflammatory Bowel Disease

Brian A. Hemstreet

KEY CONCEPTS

KEY CONCEPTS

①The exact cause of inflammatory bowel disease (IBD) is unknown. Proposed causes include infectious, genetic, and environmental factors, as well as alterations in intestinal epithelium function and systemic immune dysregulation.

②Ulcerative colitis (UC) is confined to the rectum and colon, causes continuous lesions, and affects primarily the mucosa and the submucosa. Crohn's disease (CD) can involve any part of the GI tract, often causes discontinuous (skip) lesions, and is a transmural process that can result in fistulas, perforations, abscesses, or strictures.

③Common GI complications of IBD include rectal fissures, fistulas (CD), perirectal abscess (UC), toxic megacolon (UC), and colon cancer. Extraintestinal manifestations include hepatobiliary complications, arthritis, uveitis, skin lesions (including erythema nodosum and pyoderma gangrenosum), osteoporosis, anemia, and aphthous ulcerations of the mouth.

④The severity of UC may be assessed by stool frequency, presence of blood in stool, fever, pulse, hemoglobin, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), abdominal tenderness, and radiologic or endoscopic findings. The severity of CD can be assessed using similar parameters, in addition to the CD Activity Index, which includes stool frequency, presence of blood in stool, endoscopic appearance, and physician's global assessment.

⑤The goals of IBD treatment are resolution of acute inflammation and complications, alleviation of systemic manifestations, maintenance of remission, and improvement in quality of life (QOL).

⑥The first line of treatment for mild-to-moderate extensive UC consists of oral aminosalicylates (ASAs) or oral controlled-release budesonide with prednisone as an alternative. Mesalamine enemas or suppositories are preferred for distal disease. Mesalamine is less effective for CD. Controlled-release budesonide or a tapering course of prednisone with or without azathioprine is preferred as a first-line agent for mild-to-moderate CD confined to the terminal ileum and/or ascending colon. Patients with more diffuse disease can be managed by a tapering course of prednisone with or with azathioprine.

⑦Systemic corticosteroids are often required for acute moderate to severe UC or CD. The duration of steroid use should be minimized and the dose tapered gradually over 3 to 4 weeks if possible.

⑧Infliximab, adalimumab, golimumab, ozanimod, and vedolizumab are treatment options for high-risk or moderate-to-severe active UC in outpatients and for those patients with UC who are corticosteroid dependent. Azathioprine or mercaptopurine may be used for maintenance of remission in UC as an alternative to or in combination with tumor necrosis factor-alpha (TNF-α) inhibitors, and in patients failing ASAs or with corticosteroid dependency. Vedolizumab with or without an immunomodulator may also be used as initial therapy or for patients failing TNF-α inhibitors. Tofacitinib is used for patients with moderate-to-severe UC who have failed TNF-α inhibitors.

⑨IV continuous infusion of cyclosporine or infliximab may be effective in treating severe colitis that is refractory to corticosteroids as an option to delay or prevent the need for surgery.

⑩Aminosalicylates may prevent recurrence of acute UC in many patients, while corticosteroids are ineffective for this purpose.

⑪Treatments for high-risk or moderate-to-severe CD include infliximab, adalimumab, certolizumab, and vedolizumab. Methotrexate, azathioprine, or mercaptopurine may be used for inadequate response or to reduce steroid dosage and in combination with TNF-α inhibitors; ustekimumab (patients failing other therapies); metronidazole (for perineal or colonic disease); and cyclosporine (for refractory disease) may be used.

BEYOND THE BOOK

BEYOND THE BOOK

Several online resources about IBD are available for both patients and providers. Visit the Crohn's and Colitis Foundation webcast (http://www.crohnscolitisfoundation.org/resources/webcasts.html) and watch one the following videos.

a. IBD: Diet and nutrition
b. "Ulcerative Colitis 101"
c. "Crohn's Disease 101"
d. Comprehensive Care for IBD Wellness: Integrating Diet and Complementary Therapies

Identify three things you would use to educate a patient with IBD based on the information provided in the video.

INTRODUCTION

There are two forms of idiopathic inflammatory bowel disease (IBD): (a) ulcerative colitis (UC), a mucosal inflammatory condition confined to the rectum and colon, and (b) Crohn's disease (CD), a transmural inflammation of the GI tract that can affect any part, from the mouth to the anus.

EPIDEMIOLOGY

IBD is most prevalent in Western countries and in areas of northern latitude.[1] Rates of IBD are highest in North America, Northern Europe, and Great Britain.[1,2] The incidence of IBD is increasing worldwide, especially in Westernized and newly industrialized countries.[2-4] CD has an incidence of 6 to 15.5 cases per 100,000 persons per year and a prevalence of 3.6 to 214 per 100,000 persons per year.[1,2] The incidence of UC ranges from 1.2 to 20 cases per 100,000 persons per year with a prevalence of 7.6 to 246 per 100,000 persons per year.[1] Although most epidemiologic studies combine ulcerative proctitis with UC, 17% to 49% of cases are classified as proctitis.

Both sexes are affected somewhat equally with IBD, although 20% to 30% more women are affected with CD and slightly more males (60%) are affected with UC.[2] Both UC and CD tend to have bimodal distributions in age of initial presentation. The peak incidence generally occurs in the second (CD) or third (UC) decade of life, with a second peak occurring between 60 and 70 years of age.[1-3] A higher incidence of IBD occurs in the Jewish population, while Black and Asian patients have a relatively similar, and possibly lower, incidence of IBD compared to White pateints.[2-4]

ETIOLOGY

① The exact etiology of UC and CD is unknown; however, there are similar factors believed responsible for both conditions. The major theories behind the cause of IBD involve a combination of infectious, genetic, environmental, and immunologic factors. This may involve abnormal regulation of the innate immune response or a reaction to various antigens.[4-7] The microflora of the GI tract may provide an environmental trigger to activate inflammation in genetically susceptible individuals and is highly implicated in the development of IBD.[4,7]

Infectious Factors

Microorganisms are proposed to be a major factor in the initiation of inflammation in IBD. In general, there is thought to be shift toward the presence of more proinflammatory bacteria in the GI tract, often referred to as dysbiosis.[5-7] Patients with IBD have a decreased number, richness, and diversity of intestinal microbiotica compared with those without IBD as well as increases in aggressive bacterial groups and presence of mucosal and intraepithelial bacteria.[1,5-7] The development and composition of the intestinal microbiotica may also be influenced by dietary factors.[8] The pathogenesis of IBD may involve a loss of tolerance toward normal GI bacterial flora.[1,5-7]

Microorganisms may play a key role in the development of IBD. Suspect infectious agents include viruses, protozoans, mycobacteria such as *Mycobacterium paratuberculosis* or *avium*, and other bacteria such as *Ruminococcus gnavus*, *Ruminococcus torques*, *Listeria monocytogenes*, *Fusobacterium varium*, *Chlamydia trachomatis*, and adherent invasive *Escherichia coli*.[4–10] Patients with CD typically have circulating antibodies to *Saccharomyces cerevisiae*, which demonstrates some immunologic response to intestinal organisms.[5] Bacterial gene products may promote alteration of the intestinal barrier while bacterial antigens or ligands may include and propagate the inflammatory response.[5-7,10] Appendectomy has been associated with an increase in the risk of CD in White and Middle Eastern patients, while being protective against UC in White patients.[2]

Genetic Factors

Genetic factors play a significant role in the predisposition to IBD. Studies of monozygotic twins demonstrate a high concordance rate of IBD in both individuals (particularly CD).[1,12] First-degree relatives of patients with IBD may have up to a 20-fold increase in the risk of disease and risk is extended to second- and third-degree relatives.[5,13] The nucleotide-binding oligomerization domain protein 2 (NOD2), a key component involved in pathogen recognition in the innate immune system, is a major contributor of genetic predisposition to CD.[4,10,11] Other genes involved in the innate immune system autophagy, such as ATG16L1 and IRGM, as well as genes involved in the interleukin (IL) biologic pathway such as polymorphisms of the IL-23 receptor IL-23R, and IL-12B, STAT3, and CCR6, are strongly associated with CD and possibly UC (IL-23R).[1,5,10,11] The major genetic region for UC is on chromosome 6p21, in the major histocompatibility region, near human leukocyte antigen (HLA) class II genes.[10] Alterations in the genes encoding for IL-10 and the IL-10 receptor have been implicated in UC.[10,11] Emerging areas of interest in IBD pathogenesis are the role of microRNAs and the interface between environmental factors and peroxisome proliferator-activated receptors (PPARs).[12,13]

Immunologic Mechanisms

Potential immunologic mechanisms contributing to IBD include both autoimmune and nonautoimmune phenomena. NOD proteins involved in recognition of organisms and toll-like membrane receptors (TLRs) are involved in intestinal surveillance and can lead to release of antibacterial peptides such as defensins, among other functions.[1,5] Reduction in defensin secretion by Paneth cells is thought to be one contributing factor in the loss of effective intestinal barrier function.[5,14] Consequently, the bowel wall in CD is infiltrated with lymphocytes, plasma cells, mast cells, macrophages, and neutrophils, often leading to formation of granulomas. Similar infiltration has been observed in the colonic mucosal layer in patients with UC. Given that inflammation is limited to the colon in UC, dysfunction of colonocytes is highly implicated.[1] The colonic mucosal layer in UC may be thinner and less effective in protecting the epithelial cells. This may be due to reduced mucin secretion secondary to defective goblet cell differentiation.[1,5] Autoimmune features may be directed against mucosal epithelial cells or against neutrophil cytoplasmic elements. Innate lymphoid cells are also thought to possibly play a role in IBD pathogenesis.[1,5]

Antineutrophil cytoplasmic antibodies are found in a high percentage of patients with UC (70%) and less frequently in CD.[1,3,6,10] Overproduction of circulating IgG1 antibodies in UC may react with epithelium in the eyes, skin, joints, and biliary tract.[1] Dysfunction or reduced expression of the PPAR *γ* in colonocytes may play a role in this process.[1,13]

Th1 cytokine activity is excessive in CD and increased expression of interferon-γ in the intestinal mucosa and excess production of IL-12, IL-17A, and IL22 are features of the immune response in CD.[3,5,10] In contrast, Th2 cytokine activity is excessive with UC.[1,5] This is mediated by excess production of IL-13, which contributes to epithelial cell dysfunction by enhancing natural killer T-cell cytotoxicity, and IL-5, which is involved with eosinophil recruitment and activation.[1] Activated epithelial cells secrete a variety of substances involved in the recruitment of inflammatory cells, including IL-1β, epithelial neutrophil-activating peptide 78, IL-8, and monocyte chemoattractant protein 1.[1]

Tumor necrosis factor-alpha (TNF-*α*) is a pivotal proinflammatory cytokine that is increased in the mucosa and intestinal lumen of patients with CD and UC. TNF-*α* can recruit inflammatory cells to inflamed tissues, activate coagulation, promote the formation of granulomas in patients with CD, and possibly modify epithelial cell apoptosis.[1,3,5,10]

Psychological Factors

Complex interactions between the enteric and central nervous systems, as well as contributions from the endocrine and immune systems can lead to alterations in secretion, mobility, and alterations in the intestinal barrier in patients with IBD.[15,16] Mental health changes, particularly stress, possibly correlate with disease flares in IBD, but whether psychological factors are true etiologic factors in the pathophysiologic process is unclear.[15-17] Pain, anxiety, and depression are more common in patients with IBD compared to the general population, and are reported in up to 19% to 21% of patients.[15] In some instances symptoms of mood disorders, such as anxiety, may precede the onset of IBD symptoms.[16] Perceived stress has a great bearing on frequency of symptomatic flares.[17] While perceived stress and psychological factors may not be a direct cause of IBD, they significantly affect QOL.[16] This is compounded by the need for surgical intervention and temporary or permanent ostomy placement in young patients. Patients should be screened for the presence of anxiety and depression as part of their ongoing assessment, and have ongoing assessment of their QOL. Stress reduction should be an integral part of the treatment approach for IBD symptoms.[16]

Lifestyle, Dietary, and Drug-Related Causes

Several theories regarding dietary influence on the development of IBD have been proposed. Intake of refined sugars and animal fats has been associated with development of CD, while increased protein intake has been associated with a higher risk of developing IBD.[8,9] Diet composition and food derivatives may directly influence the makeup of the gut microbiotica, alter intestinal permeability, and affect immune function possibly triggering IBD.[8,9] Diets low in fruits and vegetables and high in ω-6 polyunsaturated fats may increase the risk of CD.[8] Changes in expression of the aryl hydrocarbon receptor, a transcription factor activated by dietary ligands and involved in the maintenance of the innate immune response, may increase development of IBD.[8] Interest has arisen in vitamin D deficiency as a possible cause of IBD given that vitamin D is involved with NOD2 gene induction.[9] Diets low in fermentable oligo-, di-, and monosaccharides and polyols, referred to as FODMAPs, improve IBD symptoms in some patients by reducing the osmotic load and fermentation of these sugars.[8] Tea or coffee consumption are protective against development of IBD in Asian patients.[2,8]

Smoking plays an important but contrasting role in UC and CD. It appears to be protective for UC and is associated with fewer disease flare-ups and reduced disease severity.[1,2,10] The risk of developing UC is increased for 2 to 3 years after smoking cessation in patients without IBD. In contrast, smoking is associated with increased frequency and severity of CD, and appears to worsen ileal disease more than colonic.[4,10] Patients with CD who stop smoking have a disease severity that is similar to nonsmokers. Smoking cessation should be offered to all patients. There are data to support transdermal nicotine replacement as an adjunctive therapy in UC.[18]

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) may trigger disease occurrence or lead to disease flares by impairing mucosal barrier protective mechanisms.[25,30] Alteration in platelet function, release of inflammatory mediators, and alteration in the microvascular response to stress are other potential mechanisms of worsening of IBD. Cyclooxygenase-2 inhibitors and cyclooxygenase-1 inhibitors increase risk; however, it is unclear whether cyclooxygenase-2 inhibitors may be safer in select patients with IBD.[2] Despite the association between NSAID use and IBD flares, there is conflicting evidence regarding the consistency of this association.[19] There was no major impact on clinical outcomes with daily use of aspirin in patients with IBD.[20] Use of NSAIDs may be warranted in some patients with IBD, particularly those with arthritic symptoms, if the benefit outweighs the potential risk of disease flare. Oral contraceptives may also confer increased risk of IBD in susceptible patients.[22,23]

Development of IBD in White patients is associated with antibiotic use in childhood, while risk may be reduced in Asian and Middle Eastern patients.[2] There is a higher association of antibiotic use with development of CD.[21] Since antibiotics alter the intestinal flora, this appears to be a viable mechanism; however, delineating antibiotics as a causative factor is difficult given that symptoms may not manifest for several weeks to years following a treatment course. Furthermore, antibiotics may induce *Clostridioides difficile* infection, which is a cause of colitis. Patients presenting with severe diarrhea for whom a diagnosis of IBD is being entertained should be asked about recent antibiotics, and should be tested for *C. difficile* infection.

PATHOPHYSIOLOGY

UC and CD differ in two general respects: the extent and distribution of inflammation within the GI tract and depth of involvement within the bowel wall. Confusion in the diagnosis can occur, particularly when the inflammation is limited to the colon. For patients in whom it cannot be determined whether they have UC or CD, they are often classified as indeterminate colitis.[1] Table 52-1 compares pathologic and clinical findings of the two diseases.

TABLE 52-1

Comparison of the Clinical and Pathologic Features of Crohn's Disease and Ulcerative Colitis

Feature	Crohn's Disease	Ulcerative Colitis
Clinical		
Malaise, fever	Common	Uncommon
Rectal bleeding	Common	Common
Abdominal tenderness	Common	May be present
Abdominal mass	Common	Absent
Abdominal pain	Common	Unusual
Abdominal wall and internal fistulas	Common	Absent
Distribution	Discontinuous	Continuous
Aphthous or linear ulcers	Common	Rare
Pathologic		
Rectal involvement	Rare	Common
Ileal involvement	Very common	Rare
Strictures	Common	Rare
Fistulas	Common	Rare
Transmural involvement	Common	Rare
Crypt abscesses	Rare	Very common
Granulomas	Common	Rare
Linear clefts	Common	Rare
Cobblestone appearance	Common	Absent

Ulcerative Colitis

② Ulcerative colitis is confined to the rectum and colon and affects the mucosal and the submucosal layers. The disease distribution upon initial diagnosis is 30% to 60% proctitis, 16% to 45% left-sided colitis, and 14% to 35% have extensive colitis, also referred to as pancolitis.[1] In some instances, a short segment of terminal ileum may be inflamed; this is referred to as *backwash ileitis*. Unlike CD, the deeper longitudinal muscular layers, serosa, and regional lymph nodes are not usually involved.[1] Fistula, perforation, or obstruction is uncommon because of the more superficial pattern of inflammation.

In UC, abscesses form in the crypts of the mucosa occurs (crypts of Lieberkuhn) secondary to infiltration of lymphocytes, plasma cells, and granulocytes.[1] Crypt abscesses are usually visible only with microscopy but may be visible when coalescence results in ulceration. Extension and coalescence of ulcers may surround areas of uninvolved mucosa, causing *pseudopolyp* formation. Mucosal damage and friability in UC can result in significant diarrhea and bleeding, although a small percentage of patients experience constipation.

③ Complications of UC may be local, including hemorrhoids, anal fissures, or perirectal abscesses, and are more likely to be present during active colitis.

A major complication is toxic megacolon, which is a segmental or total colonic distension of greater than 6 cm with acute colitis and signs of systemic toxicity.[1,24] It occurs in up to 7.9% of UC patients admitted to hospitals and results in death rates of up to 8% if not medically or surgically treated.[24] Patients typically have a high fever, tachycardia, distended abdomen, elevated white blood cell count, and a dilated colon observed on x-ray.[24] Colonic perforation may occur with or without toxic megacolon and is a greater risk with the first episode. Another infrequent major complication is massive colonic hemorrhage. Colonic stricture, sometimes with clinical obstruction, may also complicate long-standing UC.

The risk of colonic dysplasia with transition to colorectal carcinoma (CRC) is two to six times greater for patients with chronic UC with colonic involvement compared with the general population.[25] CRC is responsible for 10% to 15% of deaths in patients with UC.[26] Patients with ulcerative proctitis or proctosigmoiditis are generally not considered to be at increased risk.[25,26] The cumulative risk of developing CRC in patients with chronic UC may be as high as 8% at 20 years.[26] Risk factors for CRC include young age at onset, longer duration of disease, greater extent of colonic involvement, presence of primary sclerosing colangitis (PSC), active histological inflammation, family history of a first-degree relative diagnosed with CRC prior to age 50, history of dysplasia, colonic strictures, pseudopolyps, a shortened tubular colon, and male gender.[26] Screening colonoscopy with multiple biopsies should be performed at 8 years after onset of pancolitis or 15 years following onset of left-sided UC or CD-related colitis.[32,33] Patients with PSC, extensive colitis with active endoscopic or histologic inflammation, a history of dysplasia, or a family history of a first-degree relative diagnosed with CRC prior to age 5 should undergo yearly colonoscopy.[26]

Crohn's Disease

Crohn's disease is characterized as a transmural inflammatory process. The terminal ileum is the most common site of the disorder, but it may occur in any part of the GI tract from mouth to anus.[3,10,27,28] Patients often have areas of normal bowel separating segments of diseased bowel resulting in discontinuous disease. The "cobblestone" appearance of the bowel wall results from deep mucosal ulceration intermingled with nodular submucosal thickening.

Small bowel stricture and subsequent obstruction is a complication that may require surgery. Fistula formation is also common, occurring much more frequently than with UC.[10,27] Fistulas often occur in highly inflamed areas, where loops of bowel become matted together by fibrous adhesions. Perianal fistulas may occur in up to 26% of patients within 20 years of diagnosis.[27] Fistulas may connect a segment of the GI tract to skin (enterocutaneous), two segments of the GI tract (enteroenteric), or the intestinal tract with the bladder (enterovesicular) or vagina.

Bleeding with CD is usually not as severe as with UC, although patients with CD may develop hypochromic anemia. The risk of carcinoma is increased but not as greatly as with UC, however patients with CD and a personal history of dysplasia or PSC are at higher risk, and chromoendoscopy should be used during colonscopy.[26]

Nutritional deficiencies are common with CD.[28-30] Reported deficiencies include folate, vitamin B_{12}, vitamins A and D, calcium, magnesium, iron, and zinc.[37] Major contributing factors include decreased food intake, intestinal loss, malabsorption, hypermetabolic state, drug-nutrient interactions, and those receiving long-term total parenteral nutrition.[28-30]

Extraintestinal Manifestations of IBD

Both forms of IBD are associated with development of symptoms and organ involvement outside of the GI tract referred to as extraintestinal manifestations.

Hepatobiliary Complications

Hepatobiliary complications are commonly found in patients with IBD.[1,27,31-33] Hepatic complications include non-alcoholic fatty liver disease, pericholangitis, autoimmune hepatitis, liver abscess, and cirrhosis. Biliary complications include PSC, cholangiocarcinoma, and cholelithiasis.[1,31,32] Fatty infiltration of the liver may result from malabsorption, protein-losing enteropathy, or corticosteroid use, and may be found in up to 50% of patients with IBD.[31] PSC is associated with progressive fibrosis of intrahepatic and extrahepatic bile ducts in 4% of patients with UC.[31] Cirrhosis may result from cholangitis or chronic active hepatitis. Often the severity of hepatic disease does not correlate with GI disease activity. Gallstones occur in up to 34% of patients with CD (particularly with terminal ileal disease) and are related to bile salt malabsorption.[31,32]

Joint Complications

Both peripheral and axial arthropathies may be present in patients with IBD. Peripheral arthritis is typically asymmetric, oligoarticular, non-erosive, and occurs in 5% to 20% of patients.[32,33] Symptoms may present prior to GI symptoms of IBD. Axial arthropathies include sacroiliitis, ankylosing spondylitis, and IBD-associated spondyloarthropathy. The prognosis is not as favorable as peripheral arthritis, as progression is common. Patients with axial involvement should be referred to a rheumatologist in order to assist in the disease management.[32]

Ocular Complications

Ocular complications including dry eye, blepharitis, iritis, uveitis, episcleritis, and conjunctivitis occur in up to 29% of patients with IBD.[1,32,33] Commonly reported symptoms with iritis and uveitis include blurred vision, eye pain, and photophobia. Episcleritis is associated with scleral injection, burning, and increased secretions. These complications may parallel the severity of intestinal disease, and recurrence after colectomy with UC is uncommon.

Dermatologic and Mucocutaneous Complications

Skin and mucosal lesions associated with IBD include erythema nodosum, pyoderma gangrenosum, aphthous ulceration, and Sweet’s syndrome.[32,33] Raised, red, tender nodules on the tibial surfaces of the legs and arms that vary in size from 1 to 5 cm are manifestations of erythema nodosum, and may occur in 4.2% to 7.5% of patients with IBD.[39]

Pyoderma gangrenosum occurs in 0.6% to 2% of patients with IBD and is characterized by skin pustules that progress to a burrowing ulcer with violaceous edges, ranging between 2 and 20 cm.[1,32,33] They can be seen on any part of the body but commonly occur on the lower extremities.

Oral lesions are found in 4% to 20% of patients with IBD.[32,33] The most common lesion seen with CD is aphthous stomatitis. The severity of these lesions tends to parallel the disease course. Sweet’s syndrome, also known as acute febrile neutrophilic dermatosis, is characterized by tender erythematous skin lesions secondary to dermal neutrophil infiltration, and is often associated with fever and a distribution on the upper trunk, face, neck, and arms.[32,33]

Hematologic, Coagulation, Pulmonary, and Metabolic Abnormalities

Patients with IBD may develop anemia, with a prevalence reported up to 74%.[1,29,32,33] The anemia may present as iron deficiency related to chronic blood loss, ongoing inflammation, malnutrition, hemolysis, or bone marrow suppression from drug treatment.[32,33] Alternatively, it may be more characteristic of anemia of chronic disease. Patients with IBD are at a 1.5 to 3.6 times higher risk of venous thromboembolism (VTE) compared with the general population.[32] This is secondary to activation of the clotting cascade and platelet activation secondary to inflammation. Occurrence of VTE is higher during disease flares and occurs more often in peripheral veins.[1,32,33] Patients should be considered for pharmacologic VTE prophylaxis when admitted to the hospital for a disease flare. Patients with IBD may be at increased risk for metabolic bone disease. Osteopenia may be present in 32% to

36% of patients, while osteoporosis is reported in 2% to 15%.[33,34] Bone disease may be related to a combination of nutritional deficiencies, especially calcium and vitamin D, chronic cytokine-related inflammatory effects on bone, disease-associated hypogonadism, and use of corticosteroids.[33,34] Pulmonary manifestations occur from the glottis all the way to the small airways, but most commonly involve the large airways and may include cryptogenic organizing pneumonia, bronchiectasis, and bronchiolitis obliterans.[32]

CLINICAL PRESENTATION

Clinical Presentation: Inflammatory Bowel Disease

The patterns of clinical presentation of IBD can vary widely. Patients may have a single acute episode that resolves and does not recur, but most patients experience acute flares with alternating periods of remission.

Ulcerative Colitis

There is a wide range of presenting symptoms in UC, ranging from mild abdominal cramping with frequent small-volume bowel movements to profuse diarrhea (Table 52-2). Most patients with UC experience intermittent bouts of illness after varying intervals of remission.

TABLE 52-2

Clinical Presentation of Ulcerative Colitis

Signs and symptoms

- Abdominal cramping
- Frequent bowel movements, often with blood in the stool
- Weight loss
- Fever and tachycardia in severe disease
- Blurred vision, eye pain, and photophobia with ocular involvement
- Arthritis
- Raised, red, tender nodules that vary in size from 1 cm to several centimeters

Physical examination

- Hemorrhoids, anal fissures, or perirectal abscesses may be present
- Iritis, uveitis, episcleritis, and conjunctivitis with ocular involvement
- Dermatologic findings with erythema nodosum, pyoderma gangrenosum, or aphthous ulceration

Laboratory tests

- Decreased hematocrit/hemoglobin
- Increased ESR, CRP, and fecal calprotectin
- Leukocytosis and hypoalbuminemia with severe disease
- (+) perinuclear antineutrophil cytoplasmic antibodies

④ While various disease classifications for UC exist, a standard disease severity scoring system is not universally accepted.[1,18,35] The American College of Gastroenterology (ACG) UC Activity Index uses designations of mild, moderate-severe, and fulminant disease activity using clinical signs and symptoms and laboratory data[18]:

1. Mild: Fewer than four stools daily, with intermittent blood, mild or occasional urgency, normal erythrocyte sedimentation rate (ESR <30 mm/hr [8.3 μm/s]), normal hemoglobin, and elevated C-reactive protein (CRP) and fecal calprotectin (FC).

2. Moderate-Severe: More than six stools per day with frequent blood and urgency, fever, tachycardia, anemia, elevated CRP and FC, ESR greater than 30 mm/hr (8.3 μm/s).

3. Fulminant: More than 10 bowel movements per day with continuous bleeding and urgency, toxicity, abdominal tenderness, requirement for transfusion, elevated CRP and FC, and possible colonic dilation.

Guidelines from the American Gastroenterological Association (AGA) focusing specifically on moderate-to-severe UC utilize similar definitions; however, they define a subset of severe patients with acute severe UC (ASUC) as requiring hospitalization and having greater than six bloody stools per day and at least one marker of systemic toxicity, including heart rate greater than 90 beats per minutes, temperature greater than 37.8°C, hemoglobin less than 10.5 g/dL (105 g/L; 6.52 mmol/L), and/or ESR greater than 30 mm/hr (8.3 µm/s).[35]

A clinical care pathway for UC assesses the severity of UC based on risk for colectomy.[36] Patients are stratified according to low risk for colectomy (limited anatomic extent and mild endoscopic disease) or high risk for colectomy (extensive colitis, age less than 40 years, deep ulcers, high ESR/CRP, steroid dependence, history of hospitalization, and *C. difficile* or cytomegalovirus infection).

Determining disease extent, that is, which sections of the colon are involved, is important. This is accomplished via endoscopy. Patients with "distal" disease have inflammation limited to areas distal to the splenic flexure (also referred to as *left-sided* disease), while those with "extensive disease" have inflammation extending proximal to the splenic flexure.[1,18] Inflammation confined to the rectal area is referred to as *proctitis*, while disease involving the rectum and sigmoid colon is referred to as *proctosigmoiditis*. Inflammation of the majority of the colon is called *extensive disease*, sometimes referred to as *pancolitis*. Disease activity may be assessed upon endoscopy using common scoring systems, such as the UCEIS or Mayo Score.[18]

The diagnosis of UC is made on clinical suspicion and confirmed by biopsy, stool examinations, sigmoidoscopy or colonoscopy, or barium radiographic contrast studies.[35,37] Evaluation of CRP, and FC, a protein released during leukocyte trafficking, may also assist in identifying the presence of intestinal inflammation, and are also helpful in monitoring response to therapy.[37] The presence of extraintestinal manifestations may also aid in establishing the diagnosis.[1,18,32,33]

Crohn's Disease

The time between the onset of CD complaints and the initial diagnosis may be as long as 3 years. The patient typically presents with diarrhea and abdominal pain. Hematochezia occurs in about one-half of patients with colonic involvement and much less frequently when there is no colonic involvement. A patient may first present with a perirectal or perianal lesions, or extraintestinal manifestations in up to 50% of cases[10] (Table 52-3). The diagnosis should also be suspected in children with growth retardation, especially with abdominal complaints.

TABLE 52-3

Clinical Presentation of Crohn's Disease

Signs and symptoms

- Malaise and fever
- Abdominal pain
- Frequent bowel movements
- Hematochezia
- Fistula
- Weight loss and malnutrition
- Arthritis

Physical examination

- Abdominal mass and tenderness
- Perianal fissure or fistula

Laboratory tests

- Increased white blood cell count, ESR, CRP, and fecal calprotectin
- (+) anti–*Saccharomyces cerevisiae* antibodies

Much like UC, global classification guidelines for scoring severity of active CD are not available. For patients with luminal nonfistulizing CD, the Crohn's Disease Activity Index (CDAI) is used most often to gauge response to therapy and determine remission and is employed mostly in the research setting. This score system ranges from 0 to 600, with score greater than 150 defined as active disease. The Harvey-Bradshaw Index (HBI) is another scoring system that is also used for CD, and tends to correlate well with the CDAI. A decrease of 3 points in the HBI is defined as a clinical response with complete remission defined as a score of less than 4. Treatment guidelines use the presence of signs and symptoms as their marker for disease activity and severity.[27]

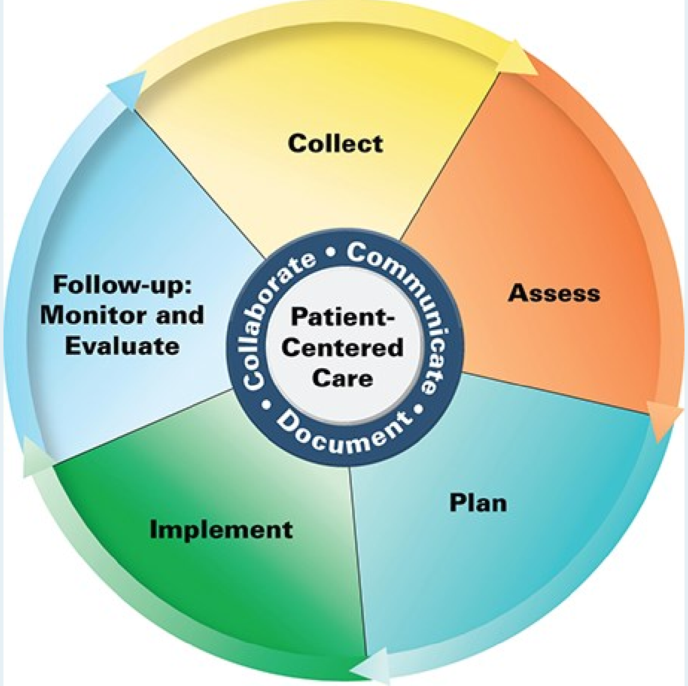
The classification of CD severity is similar to UC.[3,10,27] Patients with mild-to-moderate CD are typically ambulatory and have no evidence of dehydration, systemic toxicity, less than 10% loss of body weight, or abdominal tenderness, mass, or obstruction. This correlates to a CDAI of 150 to 220. Moderate-to-severe disease is considered in patients who fail to respond to treatment for mild-to-moderate disease or those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe-to-fulminant CD is classified as the presence of persistent symptoms or evidence of systemic toxicity despite corticosteroid or biologic treatment or presence of cachexia, rebound tenderness, intestinal obstruction, or abscess with a CDAI more than 450. Disease activity may be assessed and correlated by evaluation of CRP concentrations.

Similar to UC, the AGA has developed a clinical decision support tool for assessing CD severity.[38] Patients are stratified as low risk (age at initial diagnosis over 30 years, limited anatomic involvement, no perianal and/or severe rectal disease, superficial ulcers, no prior surgical resection, and no stricturing and/or penetrating disease) or moderate to high risk (age at initial diagnosis less than 30 years, extensive anatomic involvement, perianal and/or severe rectal disease, deep ulcers, prior surgical resection, stricturing and/or penetrating disease).

The course of CD is characterized by periods of remission and exacerbation. Patients may be symptom-free for years, while others experience chronic symptoms in spite of medical therapy. As with UC, the diagnosis of CD involves a thorough evaluation using laboratory, endoscopic, and radiologic testing to detect the extent and characteristic features of the disease.[10,27,37,38] Small bowel involvement, strictures detected on radiographs, and presence of fistulae are characteristic of CD.

PATIENT CARE PROCESS

Patient Care Process for Inflammatory Bowel Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, weight, vital signs)
- Patient symptoms, including evidence of abdominal pain, stool frequency, presence of hematochezia, weight loss, or extraintestinal manifestations
- Patient medical, family, and social history (in particular tobacco use)
- Surgical operations (site, date, procedure) and abdominal imaging findings (CT, MRI, ultrasound)
- Thorough medication history at hospital admission (include prescription, non-prescription medications, and other substances), and drug allergies and intolerances
- Laboratory results for evidence of inflammation (CRP, ESR, WBC), major organ function (particularly kidney and liver), hemoglobin and hematocrit, nutritional status (serum albumin and transferrin), vaccination status, pregnancy status, and pANCA or anti-*Saccharomyces cerevisiae* antibodies if initial diagnostic workup, and pharmacogenomics status for TPMT, if applicable

Assess

- Determine severity of illness based on symptoms, vital signs, stool frequency, and inflammatory markers. Consider use of Crohn’s Disease Activity Index to assess disease progress. Include assessment of fluid and electrolyte status
- Determine extent and location of inflammation in the gastrointestinal tract based on endoscopic and imaging procedures
- Assess if extraintestinal disease manifestations and comorbidities are present that may affect section and outcomes of medication regimens
- Evaluate current medication regimen for potential drug-induced exacerbating factors and for efficacy and toxicity of current IBD treatment regimen
- Assess if disease complications are present that may require surgical intervention (abscess or fistulae)
- Estimate creatinine clearance for drug dosing

Plan[*]

- Determine goals of therapy with monitoring parameters for each goal
- Based on severity and location of Illness, determine the appropriate medications to induce and maintain remission considering severity and site of disease (Figs. 51-1 and 51-2)
- Initiate adjunctive medications for pain and diarrhea, if needed
- Check for adverse drug reactions and interactions and dose adjustments based on end-organ function (Table 51-4)

Implement

- Initiate medications for short-term induction of remission and subsequent maintenance
- Discontinue medications that may be exacerbating symptoms
- Provide patient education on appropriate use of oral, parenteral, or rectally administered medications
- Assure that corticosteroids doses are tapered during discontinuation

Follow-up: Monitor and Evaluate

- Determine if patient shows improvement in the signs and symptoms within 24 to 48 hours for hospitalized patients, and 7 to 14 days for outpatients
- Evaluate laboratory parameters for evidence of drug efficacy and potential toxicity
- Monitor for adverse effects of medications
- Assess adherence to current medication regimen and address barriers to medication use
- Determine the need for dose reduction or tapering of medications intended for short-term use, such as corticosteroids

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcomes

⑤ The clinician must have a clear concept of realistic therapeutic goals for each patient with IBD. Goals may relate to resolution of acute inflammatory processes, resolution and prevention of complications (eg, fistulae, abscesses, and CRC), alleviation of extraintestinal manifestations, maintenance of remission, or surgical palliation or cure.

When determining goals of therapy and selecting therapeutic regimens, it is important to understand the natural history of IBD.[1,18,27,39] Some cases of acute UC are self-limited. Following remission, up to 43% of patients may experience relapse in the first year, and almost half may require hospitalization at some point during their disease course.[39] Being young at the time diagnosis, female sex, presence of extraintestinal manifestations, nonsmoking status, and higher levels of education have been associated with higher risk of relapse.[39] With severe colitis, improvement without treatment cannot be expected. The response to medical management of toxic megacolon is variable and emergent colectomy may be required. CD tends to be progressive and destructive, with only 20% to 30% having an indolent course.[3,9,27] Patients at risk for progression of CD include young age at diagnosis, extensive bowel involvement, perianal or severe rectal disease, or stenosis.[27] Up to 80% of patients will require hospitalization at some point during their disease course, and there are high rates of steroid dependence and the need for surgical intervention.

There has been a movement toward use of the "Treat-to-Target" approach.[10,40] This involves use of specific targets, such as mucosal healing and endoscopic remission, or resolution of symptoms such as abdominal pain and diarrhea, as the main indicators of treatment efficacy. Mucosal healing, defined as the absence of ulceration, has become an important target and is accessed via endoscopy with specific scoring systems used to determine if this outcome has been assessed. Mucosal healing can be used as a monitoring parameter for treatment efficacy, particularly in CD, and if achieved may be predictive of steroid free sustained remission.[27,40] Biomarkers, such as CRP and FC, have also become important adjunctive monitoring parameters to endoscopic approaches.[27,37,40]

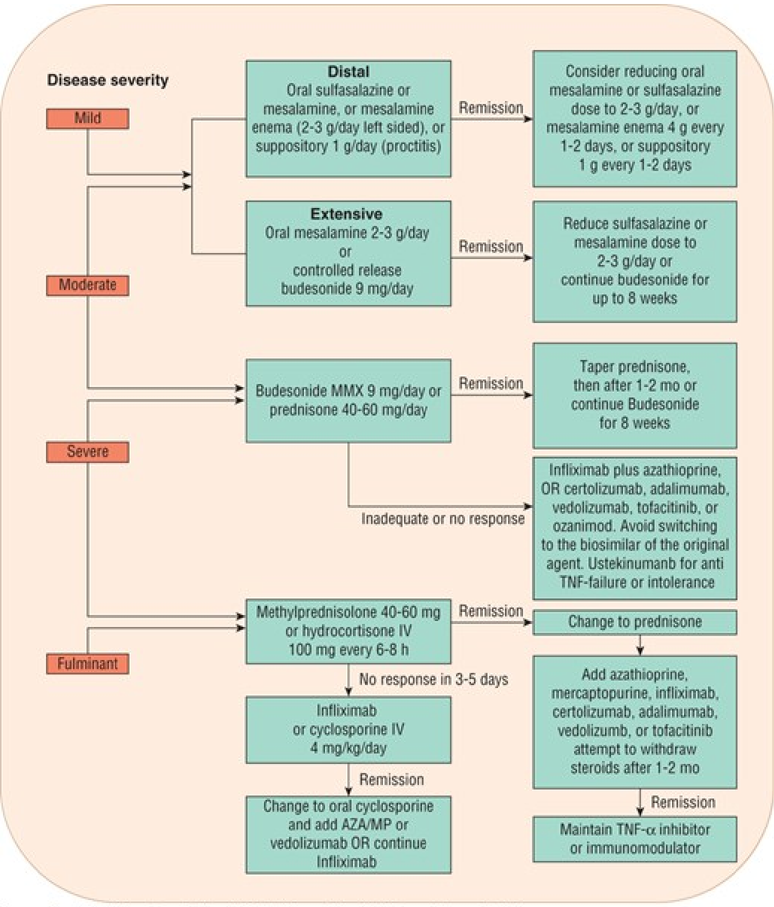
General Approach to Treatment

⑥ Treatment of IBD centers on agents used to suppress the inflammatory process, induce, and then maintain disease remission. The severity and extent of the disease should be taken into account, as this will often dictate the dose, route, frequency, and formulation of drug therapies that will be most effective. Patient preference for different drug formulations and cost of therapies should also be taken into account.

Surgical procedures are sometimes performed when active disease is inadequately controlled with drugs, or when the required drug dosages pose an unacceptable risk of adverse effects. Nutritional considerations are also important because many patients may develop malnutrition. A variety of adjunctive therapies may be used to address complications or symptoms of IBD.

FIGURE 52-1

Treatment approaches for ulcerative colitis.



Disease severity
Mild
Moderate
Severe
Fulminant
Distal
Oral sulfasalazine or mesalamine, or mesalamine enema (2-3 g/day left sided), or suppository 1 g/day (proctitis)
Remission
Consider reducing oral mesalamine or sulfasalazine dose to 2-3 g/day, or mesalamine enema 4 g every 1-2 days, or suppository 1 g every 1-2 days
Extensive
Oral mesalamine 2-3 g/day or controlled release budesonide 9 mg/day
Remission
Reduce sulfasalazine or mesalamine dose to 2-3 g/day or continue budesonide for up to 8 weeks
Budesonide MMX 9 mg/day or prednisone 40-60 mg/day
Remission
Taper prednisone, then after 1-2 mo or continue Budesonide for 8 weeks
Inadequate or no response
Infliximab plus azathioprine, OR certolizumab, adalimumab, vedolizumab, tofacitinib, or ozanimod. Avoid switching to the biosimilar of the original agent. Ustekinumanb for anti TNF-failure or intolerance
Methylprednisolone 40-60 mg or hydrocortisone IV 100 mg every 6-8 h
Remission
Change to prednisone
No response in 3-5 days
Add azathioprine, mercaptopurine, infliximab, certolizumab, adalimumab, vedolizumb, or tofacitinib attempt to withdraw steroids after 1-2 mo
Infliximab or cyclosporine IV 4 mg/kg/day
Remission
Change to oral cyclosporine and add AZA/MP or vedolizumab OR continue Infliximab
Remission
Maintain TNF-α inhibitor or immunomodulator

Nonpharmacologic Therapy

Nutritional Support

Malabsorption or maldigestion may occur secondary to the catabolic effects of the disease process. Patients with IBD have a fivefold higher risk of malnutrition compared to those without IBD.[28] Patients with CD have continued risk, even when their disease is quiescent, while patients with UC are more at risk during times of active disease.[30] Unnecessary food restriction during hospitalization also places patients at higher risk for malnutrition.[28] Patients who have undergone multiple small bowel resections may have reduction in the absorptive surface of the intestine (ie, "short gut"). Maldigestion with accompanying diarrhea can also occur if there is a bile salt deficiency in the gut. Patients should be screened for malnutrition upon diagnosis and assessed intermittently for the presence of micronutrient deficiencies.[30]

Elimination of specific foods that appear to exacerbate symptoms can be tried; however, exclusion diets are generally not endorsed, even in the setting of severe disease.[30] Increased intake of red meat, protein, sulfur and sulfates, and alcoholic beverages have been associated with disease flares.[8] If attempted, the elimination process must be conducted cautiously, as patients may exclude a wide range of nutritious products without adequate justification. Some patients with IBD may have lactase deficiency as well; therefore, diarrhea may be associated with intake of dairy products. For these patients, avoidance of dairy products or supplementation with lactase generally improves the patient's symptoms. Patients with small bowel strictures due to CD should avoid excessive high-residue foods, such as citrus fruits and nuts, in order to prevent obstruction. Increases in soluble fiber may induce the production of intestinal short chain fatty acids, which may have intrinsic anti-inflammatory effects.[8]

Many specific diets have been tried to improve nutritional status and symptoms in IBD. Use of diets low in FODMAPs may help improve IBD symptoms. The specific carbohydrate diet (SCD) is another option that involves restriction of all carbohydrates except monosaccharides (glucose, fructose, and galactose), as well as restriction of milk, canned fruits and vegetables, and processed meats.[9,28,30] Some studies have demonstrated improvement in symptoms and inflammation; however, these diets are difficult to follow and patient adherence may by problematic.[28,30] Exclusive enteral nutrition, which involves use of elemental, semi-elemental, and defined formulas, has shown some benefit in increasing nutritional status and reducing intestinal inflammation and cytokine production.[8,28,30] While this approach may lead to a greater chance of induction of remission, particularly in patients with CD, most data are in pediatric patients and are lacking regarding its use as a maintenance diet.[28,30]

Parenteral nutrition is generally reserved for patients with severe malnutrition or those who fail enteral therapy or have a contraindication to receiving enteral therapy, such as perforation, protracted vomiting, short-bowel syndrome, or severe intestinal stenosis.[30] Parenteral therapy is not preferred as primary therapy for IBD even in the setting of acute disease flares in hospitalized patients, and should be reserved for those patients with the most complicated disease.[30] Home parenteral nutrition may be necessary for patients requiring long-term therapy, particularly those with short-bowel syndrome. Parenteral nutrition is more costly and is associated with more complications, such as serious infections, compared with enteral nutrition.

Probiotic administration as an adjunctive treatment of IBD has been explored. Postulated mechanisms for using probiotics in IBD include reestablishment of normal bacterial flora within the gut, reduction in bacterial adhesion and competition for nutrients with pathogenic bacteria, production of antibacterial substances, and promotion of favorable effects on the host immune response.[7] Probiotic preparations often contain various organisms such as nonpathogenic *E. coli Nissle*, bifidobacteria, lactobacilli, *Streptococcus thermophilus*, *or Saccharomyces boulardii*. While probiotics were effective in inducing and maintaining remission in some trials for patients with UC, differences in methodology, probiotics used, and underlying treatments for IBD make comparison of trials difficult.[40,41] A formulation of *Bifidobacterium*, lactobacilli, and streptococci (VSL #3) is marketed specifically for use in UC as an adjunctive therapy and for patients who have a surgically constructed ileal pouch anal anastomosis (IPAA) to prevent or treat pouchitis.[18,41,42] Evidence of probiotic use for the induction and maintenance of CD is less compelling and has led to recommendations not supporting widespread use, but rather further investigation.[27,42] While probiotics are considered to be generally safe in patients with IBD, the added cost, requirement to take multiple doses per day, coupled with the lack of quality data to support their use, should also weigh into the decision to use them in IBD.

FIGURE 52-2

Surgery

Patients with IBD often require surgery. Surgical procedures may involve resection of segments of intestine that are affected, as well as correction of complications (eg, fistulas) or drainage of abscesses.

Rates of colectomy over 20 years UC are reported as 0.55% to 20%.[1,18,39,43] Colectomy may be necessary when the patient has disease uncontrolled by maximum medical therapy or when there are complications of the disease such as colonic perforation, toxic megacolon, uncontrolled colonic hemorrhage, or colonic strictures.[1,24,43] Colectomy may be indicated for patients with long-standing disease (greater than 8-10 years), as a prophylactic measure against the development of CRC, and for patients with premalignant changes (severe dysplasia) on surveillance mucosal biopsies.[42] Proctocolectomy, after which the patient is left with a permanent ileostomy, is generally considered curative for UC; however, the decision to perform this should take into account the effects on the patient's QOL. Restorative proctocolectomy with construction of an IPAA is the most common surgical procedure performed in UC. This procedure is typically well tolerated with approximately 29% of patients developing long-term complications such as pouchitis, pelvic floor abscess, or bowel obstruction.[43]

Surgery in patients with CD is usually reserved for patients with intractable hemorrhage, perforation, persistent or recurrent obstruction, abscess, dysplasia, cancer, or medically refractory disease.[27,44,45] The 10-year cumulative risk of surgical intervention is 40% to 55%, with the 5-year postoperative recurrent rate reported as approximately 50%.[27] The surgical procedures performed most often include resections of the major intestinal areas of involvement. Patients who undergo multiple resections of the small intestine may develop malabsorption related to short-bowel syndrome. For some patients with severe rectal or perianal disease, particularly abscesses, diversion of the fecal stream is performed with a colostomy.

TABLE 52-4

Drug Monitoring Guidelines

Drug(s)	Adverse Drug Reaction	Monitoring Parameters	Comments
Sulfasalazine	• Nausea, vomiting, headache • Rash, anemia, pneumonitis	• Folate, complete blood count • Liver function	Increase the dose slowly, over 1-2 weeks

	• Hepatotoxicity, nephritis • Thrombocytopenia, lymphoma	tests, Scr, BUN	
Mesalamine	Nausea, vomiting, headache	GI disturbances	
Corticosteroids	Hyperglycemia, dyslipidemia	Blood pressure, fasting lipid panel	Avoid long-term use if possible or consider budesonide
	Osteoporosis, hypertension, acne	Glucose, vitamin D, bone density	
	Edema, infection, myopathy, psychosis		
Azathioprine/mercaptopurine	Bone marrow suppression, pancreatitis, lymphoma	Complete blood count	Check TPMT activity or NUDT15 phenotype
	Liver dysfunction, rash, arthralgia	Scr, BUN, liver function tests, genotype/phenotype	May monitor TGN
Methotrexate	Bone marrow suppression, pancreatitis	Complete blood count, Scr, BUN	Check baseline pregnancy test
	Pneumonitis, pulmonary fibrosis, hepatitis	Liver function tests	Chest x-ray
Infliximab Adalimumab Certolizumab Golimumab	• Infusion-related reactions (infliximab), infection • Heart failure, optic neuritis, demyelination, injection site reaction, signs of infection	• Blood pressure/heart rate (infliximab) • Neurologic exam, mental status • Trough concentrations (infliximab) • Antidrug antibodies (all agents)	Need negative PPD and viral serologies
Natalizumab Vedolizumab	Infusion-related reactions	Brain MRI, mental status, progressive multifocal leukoencephalopathy	Vedolizumab not associated with PML

Ustekinumab	Infections, skin cancers	Signs/symptoms of infection, annual skin exam	Rare instances of reversible posterior leukoencephalopathy syndrome (RPLS) Avoid live vaccines
Tofacitinib	Infection, thrombosis, lymphoma, elevated cholesterol, CPK, LFTs, lymphopenia, neutropenia, anemia	Symptoms of Infection or thrombosis	Avoid live vaccines. Screen for baseline TB. Do not initiate in patients with lymphocytes < 500/mm^3(0.5 x 10^9/L), ANC <1000/mm^3(1 x 10^9/L), or hemoglobin <9 g/dL (90 g/L; 5.59 mmol/L). Monitor lipids and LFTs every 4-8 weeks. Gastrointestinal perforation has been reported with use of the XR formulation. Drug interactions with CYP3A4 and 2C19 inhibitor
Ozanimod	Infection, heart rate, blood pressure, LFTs, respiratory rate, fetal abnormalities, macular edema, headache	Symptoms of infection or respiratory dysfunction, changes in vision	Need baseline ECG, WBC, LFTs, ophthalmic assessment, and testing for varicella zoster antibodies. Contraindicated if patient has experienced MI, unstable angina, stroke, TIA, decompensated heart failure, or Mobitz type II second- or third-degree AV block, sick sinus syndrome in the last 6 months, presence of sleep apnea, and concomitant use of MAOI. Women of childbearing age should use effective contraception during and for 3 months after use

Pharmacologic Therapy

The approach to treatment of IBD should consider all aspects of each individual patient in order to maximize therapy, improve patient symptoms and QOL, and prevent complications. To ensure optimal drug therapy, an assessment of each patient's health literacy and potential barriers to understanding and adherence should be performed. Involving the patient in the care process will help to keep him or her engaged. Since patients with IBD are often seen by GI specialists or surgeons, ensuring that each provider has a current, accurate, and complete medication list will help to prevent potential medication errors. Female patients of childbearing age should discuss with their providers their goals for becoming pregnant, as this may dictate the choice of drugs used.

None of the drugs used for IBD are curative; therefore, reasonable goals of drug therapy are resolution of acute disease symptoms and induction and maintenance of remission.

Sulfasalazine is the prototypical ASA, and is composed of a sulfonamide moiety (sulfapyridine) and mesalamine (5-aminosalicylate acid [5-ASA]) joined by a diazo bond in the same molecule.[46] Sulfasalazine has been used for years to treat IBD but was originally intended to treat arthritis. It is cleaved by gut bacteria in the colon to sulfapyridine (which is mostly absorbed and excreted in the urine) and mesalamine (which mostly remains in the colon and is excreted in stool).[46,47]

The active component of sulfasalazine is mesalamine, which exerts its effects locally in the GI tract; however, the mechanism of action is not completely understood. Beneficial effects of mesalamine may include scavenging of free radicals, inhibition of leukocyte motility, interference with TNF-α, transforming growth factor-β (TGF-β) and nuclear factor κB (NF-$\kappa\beta$), suppression of IL-1 production, inhibition of leukotriene and prostaglandin production, and induction of PPARγ.[13,18,46,47]

Because the effectiveness of sulfasalazine is not related to the sulfapyridine component and since sulfapyridine is believed to be responsible for many of the adverse reactions to sulfasalazine, mesalamine can be administered alone. Given that mesalamine is rapidly and completely absorbed in the small intestine but poorly absorbed in the colon, drug formulations must be designed to deliver mesalamine to the affected areas in the GI while preventing premature absorption. Mesalamine can be used topically as an enema, to treat left-sided disease, or as a suppository for treatment of proctitis (Fig. 52-3).[48-50] The use of topical mesalamine preparations, such as enemas and suppositories, is more effective than oral preparations.[48-50] These therapies may be used concomitantly with the oral mesalamine preparations, which may result in additive efficacy in patients with UC.[49,50] Oral slow-release formulations will deliver mesalamine to the small intestine and/or colon based on the product design (Table 52-5). Slow-release oral formulations of mesalamine (eg, Pentasa) release mesalamine from the duodenum to the ileum, with up to 59% of the drug passing into the colon.[46,47] Some dose forms (Asacol, Asacol HD, Delzicol) utilize a pH-dependent coating that releases in response to intestinal pH.[46] Another tablet formulation of mesalamine (Lialda) uses a pH-dependent coating that releases at a pH of 7, in combination with a polymeric matrix core, referred to as the Multi-MatriX (MMX) system, and releases drug evenly throughout the colon also allowing for once-daily dosing.[51] A capsule formulation of mesalamine (Apriso) utilizes enteric-coated mesalamine granules in a polymer matrix for delayed and extended delivery of mesalamine to the colon and also allows for once-daily dosing.[46] Use of once-daily oral mesalamine preparations may enhance adherence, which may help to prevent relapse.[46-48] Olsalazine is a dimer of two mesalamine molecules linked by an azo bond. Mesalamine is released in the colon after colonic bacteria cleave the azo bond.[46] Balsalazide is a mesalamine prodrug that couples mesalamine with the inert carrier molecule 4-aminobenzoyl-β-alanine and is also enzymatically cleaved in the colon to release mesalamine.[46] Because the oral mesalamine formulations are delayed-release coated tablets or granules, they should not be crushed or chewed. Unlike sulfasalazine, all of these agents are safe to use for patients with sulfonamide allergies.

FIGURE 52-3

Site of activity of various agents used to treat inflammatory bowel disease.

TABLE 52-5

Agents for the Treatment of Inflammatory Bowel Disease

Drug	Brand Name	Initial Dose	Usual Range
Sulfasalazine	- Azulfidine - Azulfidine EN	- 500 mg to 1 g - 500 mg to 1 g	- 4-6 g/day - 4-6 g/day
Mesalamine suppository	Canasa	1 g	1 g daily to three times weekly
Mesalamine enema	Rowasa	4 g	4 g daily to three times weekly
Mesalamine (oral)	- Asacol HD - Apriso	- 1.6 g/day - 1.5 g/day	- 2.8-4.8 g/day - 1.5 g/day once daily

	Lialda Pentasa Delzicol	1.2-2.4 g/day 2 g/day 1.2 g/day	1.2-4.8 g/day once daily 2-4 g/day 2.4-4.8 g/day
Olsalazine	Dipentum	1.5 g/day	1.5-3 g/day
Balsalazide	Colazal	2.25 g/day	2.25-6.75 g/day
Azathioprine	Imuran, Azasan	50-100 mg	1-2.5 mg/kg/day
Cyclosporine	Gengraf Neoral, Sandimmune	2-4 mg/kg/day IV 2-8 mg/kg/day oral	2-4 mg/kg/day IV
Mercaptopurine	Purinethol, Purixan	50-100 mg	1-2.5 mg/kg/day
Methotrexate	No branded IM injection	15-25 mg IM weekly	15-25 mg IM weekly
Adalimumab	Humira	160 mg SC day 1	80 mg SC 2 (day 15), and then 40 mg every 2 weeks
Adalimumab-atto	Amjevita[a]		
Adalimumab-abdm	Cyltezo[a]		
Adalimumab-adaz	Hyrimoz[a]		
Adalimumab-afzb	Abrilada[a]		
Adalimumab-bwwd	Hadlima[a]		
Certolizumab	Cimzia[a]	400 mg SC	400 mg SC weeks 2 and 4, and then 400 mg SC monthly
Infliximab	Remicade	5 mg/kg IV	5 mg/kg weeks 2 and 6, 5-10 mg/kg every 8 weeks
Infliximab-dyyb	Inflectra		
Infliximab-abda	Renflexis		
Infliximab-qbtx	IXIFI		
Infliximav-axxq	AVSOLA		
Natalizumab	Tysabri	300 mg IV	300 mg IV every 4 weeks

Budesonide	Entocort EC capsule, Uceris tablet	9 mg orally once daily	6-9 mg daily
	Uceris rectal foam	2 mg twice daily	2 mg daily
Vedolizumab	Entyvio	300 mg IV	300 mg IV weeks 2 and 6 and then every 8 weeks
Golimumab	Simponi	200 mg SC	100 mg SC weeks 2 and 4
Ustekinumab	Stelara	Weight based initial IV dose <55 kg (260 mg), 55-85 kg (390 mg), >85 kg (520 mg)	90 mg SC every 8 weeks
Tofacitinib	Xeljanz, Xeljanz XR	10 mg twice daily or 22 mg XR for 8 weeks; may continue for max of 16 weeks	5 mg twice daily or 11 mg once daily
Ozanimod	Zeposia	0.23 mg orally once daily days 1-4, then 0.46 mg once daily days 5-7	0.92 mg orally once daily starting day 8 of therapy

[a] Not available until 2023

SC, subcutaneous; IM, intramuscular.

Picking the appropriate ASA formulation and dose of drug for the disease severity and extent is key. Enemas and suppositories, while generally more effective than oral preparations, may not be as acceptable for use, particularly by younger patients. Therefore, individuating the patient’s preference for a specific formulation should be taken into account when choosing ASA preparations. Consideration can be given to the use of once-daily products if there is evidence that multiple-daily dosing is affecting patient adherence.[18,46-51]

⑦ Corticosteroids are used to suppress acute inflammation in the treatment of IBD, and may be given parenterally, orally, or rectally.[52] They modulate the immune system and inhibit production of cytokines and mediators. It is not clear whether the most important steroid effects are systemic or local (mucosal). Budesonide is a corticosteroid that is administered orally in a controlled-release formulation designed to release in the terminal ileum or the colon depending on the product, or as a rectal foam. The drug undergoes extensive first-pass metabolism; so systemic exposure is thought to be minimized.[50,52]

Immunomodulators such as azathioprine, mercaptopurine, methotrexate, or cyclosporine are also used for the treatment of IBD (see Table 51-4). Azathioprine and mercaptopurine are effectively used in long-term treatment of both CD and UC.[1,18,27,53,54] These agents are generally reserved for patients who fail ASA therapy or are refractory to or dependent on corticosteroids. They may be used in conjunction with mesalamine derivatives, corticosteroids, TNF-α antagonists, and vedolizumab, and must be used for extended periods of time, ranging from a few weeks up to several months, before benefits may be observed.[53,54]

Cyclosporine has a short-term benefit in the treatment of acute, severe UC to avoid colectomy in patients failing corticosteroids, but has little efficacy in CD.[1,18,35] It is used initially as a continuous IV infusion of 2 to 4 mg/kg daily.[35] Cyclosporine poses a risk of nephrotoxicity and neurotoxicity. Studies evaluating tacrolimus for the treatment of IBD suggest a potential role for short-term use in patients with perianal or fistulizing CD; however, results have been variable with few data to support its routine use.[27] There are limited data to suggest routine use of tacrolimus in UC as well.[18] Methotrexate 15 to 25 mg given intramuscularly or subcutaneously once weekly may useful for maintenance therapy of CD and may result in steroid-sparing effects, while data supporting use in UC are lacking.[27,55]

Antimicrobial agents have limited roles as adjunctive therapies in IBD. Metronidazole can be used as adjunctive therapy for simple perianal fistulaes and may be combined with infliximab.[27] Risks of long-term antibiotic use include the development of antibiotic resistance, predisposition to *C. difficile* infection, and adverse effects such as neurotoxicity secondary to metronidazole use.

Biologic agents that target TNF-α have become a key class of agents in the treatment and maintenance of IBD.[56-58] Infliximab is an IgG1 chimeric monoclonal antibody that utilizes 25% murine variable regions and is administered IV. Infliximab binds TNF-α and inhibits its inflammatory effects, resulting in reductions in pro-inflammatory cytokines, such as IL-1 and IL-6. Adalimumab is also an IgG1 antibody to TNF-α; however, this agent, unlike infliximab, is fully humanized and contains no murine sequences. It is administered subcutaneously. Theoretically, the lack of a murine component in adalimumab reduces antibody development seen with use of infliximab. Certolizumab pegol is a humanized pegylated Fab fragment directed against TNF-α that is also administered subcutaneously. Golimumab is similar in structure to adalimumab and offers similar efficacy to the currently approved agents.

Biosimilars are highly similar to the FDA-approved biologic agents. There are no clinically meaningful differences in efficacy or adverse effects from the reference products. Biosimilars have a nonproprietary name plus an FDA-designated suffix consisting of four lowercase letters that have no intended meaning. Some are considered to be interchangeable with the reference product.[56] Several infliximab biosimilar agents are approved for use in UC and CD, including infliximab-dyyb, infliximab-abda, infliximab-qbtx, and infliximab-axxq. There are several adalimumab biolsimilars, including adalimumab-adbm, adalimumab-atto, adalimumab-adaz, adalimumab-afzb, and adalimumab-bwwd. Legal disputes involving the manufacturers of the adalimumab reference products have led to delays in the commercial availability of the biosimilar products.

Natalizumab and vedolizumab are biologic agents that inhibit leukocyte adhesion and migration by targeting the α_4 subunit of integrin.[59,60,70]

Vedolizumab works similar to natalizumab but is more specific for the $\alpha_{4\beta7}$ subunit of integrin, which targets leukocyte trafficking in the gut.[59]

Ustekinumab is a biologic agent that blocks IL-21 and IL-23 action by binding to the p40 protein subunit used by these cytokines.[61,62] It is approved for use in moderate-to-severe CD in patients who failed immunomodulators or corticosteroids but have not received anti-TNF therapy. It can also be used for patients who have failed anti-TNF therapy and in combination with immunomodulators. Tofacitinib inhibits intracellular Janus kinases (JK) proteins, which are responsible for the signal transduction of multiple cytokines involved in the inflammatory cascade.[63] It is approved for patients with moderate-to-severe UC who are unresponsive to TNF-α inhibitors. Ozanimod is a small molecule that inhibits sphingosine-1 phosphate (S1P) which inhibits lymphocyte egress from lymph nodes and subsequent migration to the intestinal tract.[57] It is approved for the treatment of moderate to severely active UC in adult patients.

Treatment of Ulcerative Colitis

Induction Therapy for Mild-to-Moderate Active Disease Most patients with mild-to-moderate active UC can typically be managed on an outpatient basis with oral and/or topical ASAs or oral or rectal budesonide (Fig. 51-1; Table 51-6). Mesalamine preparations are typically better tolerated than sulfasalazine and thus are often chosen preferentially as first-line therapies. For patients with extensive disease, oral once daily mesalamine is generally preferred at a dose of 2 to 3 g/day (see Table 51-2).[18,64] Doses of greater than 3 g/day are reserved for lack of response to standard doses. Topical mesalamine in an enema or suppository formulation is more effective than oral mesalamine or topical steroids for distal disease. Mesalamine suppositories will only reach to approximately 10 to 20 cm within the lower GI tract and thus are reserved for patients with proctitis. Enemas will reach to the splenic flexure and are preferred for left-sided disease. Combining suppositories or enemas with oral mesalamine preparations has additive effects and is preferred in patients with extensive or left-sided disease if patients are willing to use both preparations.[18,64] Sulfasalazine, at doses of 2 to 4 g/day, may be considered in patients already receiving it in remission, or in those with prominent arthritic symptoms.[44]

TABLE 52-6

Levels of Evidence for Therapeutic Interventions in Inflammatory Bowel Disease

Interventions	Evidence Grades[a]
Ulcerative Colitis	
Rectal mesalamine is recommended at a dose of 1 g/day for induction of remission in mildly active UC	Strong

Mesalamine enemas at a dose of 1 g/day is preferred over rectal steroids for induction of remission in mildly active left-sided colitis	Strong
Rectal mesalamine at a dose of 1 g/day in combination with oral mesalamine at a dose of 2 g/day is preferred for induction of remission of mildly active left sided UC	Conditional
Oral budesonide 9 mg/day is preferred in patients who fail or are intolerant of oral or rectal mesalamine for induction of remission in mildly active UC	Strong
High-dose mesalamine (>3 g/day) is suggested in patients who have suboptimal response to standard dose mesalamine	Conditional
Oral mesalamine at a dose of at least 2 g/day is recommended for induction of remission in patients with mildly active extensive colitis	Strong
Oral systemic corticosteroids are recommended for induction of remission in patients with UC of any extent who fail to respond to mesalamine	Strong
Sulfasalazine, mesalamine, or balsalazide is effective in maintenance of remission of distal disease; combining oral and topical mesalamine is more effective than is either alone	Strong
Sulfasalazine, olsalazine, mesalamine, and balsalazide are effective in preventing relapses in patients with mild-to-moderate extensive disease	Strong
Corticosteroids are not effective as maintenance treatment	Strong
Oral budesonide is recommended for induction of remission in patients with moderately active UC	Strong
Monotherapy with thiopurines or methotrexate is not recommended for induction therapy in patients with moderate-to-severe active UC	Strong
Infliximab, adalimumab, and golimumab are effective for induction of remission in moderate-to-severe active UC	Strong
Infliximab combined with a thiopurine is effective for induction therapy in moderately severe active UC	Strong
Tofacitinib is effective for induction and maintenance of remission for patients with moderate to severely active UC	Strong
Vedolizumab is effective for induction of remission in moderate-to-severe active UC	Strong
Tofacitinib is effective for induction of remission in patients with moderate-to-severe UC	Strong
Crohn's Disease	
Sulfasalazine is effective for treating mild-to-moderate active colonic CD	Conditional
Mesalamine has not consistently been demonstrated to be effective in active CD	Strong
Ileal release budesonide is effective for mild-to-moderate ileal or right-sided colonic disease	Strong
Metronidazole is not effective for treatment of luminal CD	Conditional
Ciprofloxacin should not be used for treatment of luminal CD	Conditional
Systemic corticosteroids are effective for short-term treatment of moderate to severely active CD	Strong
Conventional corticosteroids do not consistently achieve mucosal healing	Weak

Thiopurines should be considered for steroid sparing in CD	Strong
Azathioprine and mercaptopurine are not effective to induce short-term remission	Strong
Azathioprine and mercaptopurine are effective for maintenance of remission	Strong
TPMT testing should be considered prior to use of azathioprine or mercaptopurine	Strong
Anti-TNF agents should be given in patients refractory to azathioprine or methrotrexate	Strong
Vedolizumab with or without an immunomodulator should be considered for induction of remission in symptomatic patients	Strong
Natalizumab can be considered for induction of remission	Strong
Infliximab, adalimumab, and certolizumab are effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients	Strong
Ustekinumab should be given in moderate to severe CD in patients who fail treatment with corticosteroids, thiopurines, methotrexate, or anti-TNF agents or who have no prior exposure to anti-TNF agents	Strong
Cyclosporine, mycophenolate mofetil, and tacrolimus should not be used for CD	Strong
Methotrexate maintenance therapy (15-25 mg IM weekly) is effective for steroid sparing and for maintenance of remission	Conditional
Intravenous corticosteroids should be used for severe to fulminant CD	Conditional
Infliximab, adalimumab, and certolizumab are effective in severely active CD	Strong
Infliximab can be administered for treatment of fulminant CD	Conditional
Infliximab is effective for perianal fistulas	Strong

[a] Strong (desirable effects outweigh undesirable), conditional (uncertainty about trade-offs).

Data from Reference [6,8,18,27,35].

Controlled-release budesonide (Uceris) is an alternative for mildly active extensive UC, and is typically recommended in patients unresponsive to mesalamine. While budesonide foam may be used for distal disease, it has a limited role and is reserved for patients who are intolerant or unresponsive to topical mesalamine.[1,18,52,64] Oral budesonide MMX at a dose of 9 mg/day is preferred for patients who are unresponsive to optimized doses of mesalamine.[18,64] Oral corticosteroids in doses of 40 to 60 mg/day prednisone equivalent can be used as an alternative to budesonide for patients with moderately active extensive disease who are refractory to oral ASAs or require more rapid control of symptoms.[18,64] Topical corticosteroids, given as foams, enemas, and suppositories, while effective for patients with distal disease, are generally less effective than mesalamine but can be used for patients with tenesmus or intolerance to meslamine.[18,52,64]

Induction therapy for Moderate-to-Severe Active Disease Patients with moderate-to-severe active disease require prompt initiation of therapies to quickly suppress inflammation. While oral mesalamine products may be effective for moderately severe UC, oral budesonide MMX is the preferred alternative prior to use of more systemic corticosteroids and for moderate disease.[18,35,64] Systemic corticosteroids are an alternative for the treatment of moderate-to-severe active UC regardless of disease location or in those patients who are unresponsive to maximal doses of oral and/or topical mesalamine derivatives.[18,35] Oral doses of 40 to 60 mg prednisone equivalent daily are recommended.[18,52,64]

Use of TNF-α inhibitors or vedolizumab are the main options for patients with moderate-to-severe disease who are unresponsive to aminosalicylates or corticosteroids, or are corticosteroid dependent, and are more effective than immunomodulator monotherapy for induction of remission.[18,35] The choice of agent depends on previous exposure to biologic agents. For treatment-naive patients, infliximab or vedolizumab in combination with an immunomodulator (eg, azathioprine) is recommended preferentially.[18,35] Vedolizumab is superior to adalimumab in this setting.[65] Certolizumab is not approved for use in UC in the United States. Combining infliximab or vedolizumab with a thiopurine is more effective in inducing corticosteroid-free remission in patients with moderate-to-severe UC and is the preferred approach.[35,60] Vedolizumab should not be used in combination with TNF-α inhibitors. For patients previously exposed to infliximab, ustekinumab or tofacitinib are preferentially recommended over vedolizumab or adalimumab.[35] Ozanimod is an alternative for induction and subsequent maintenance therapy in moderate to severely active UC.[66]

Therapy for Acute Severe or Fulminant Disease Patients with ASUC or those with incapacitating symptoms require hospitalization for effective management. Under these conditions, patients generally receive nothing by mouth to promote bowel rest. Medications are given by the parenteral route, and oral sulfasalazine or mesalamine derivatives are not typically beneficial in this setting because of rapid elimination of these agents from the colon with diarrhea. Patients should be tested for *C. difficile* infection and receive VTE prophylaxis.

Systemic corticosteroids are used in the treatment of severe disease and may allow some patients to avoid colectomy. Methylprednisolone IV at a dose of 40-60 mg daily is considered a first-line agent.[35] A trial of corticosteroids is warranted in most patients before proceeding to colectomy, unless the condition is grave or rapidly deteriorating. The length of corticosteroid therapy before consideration of surgery is open to debate, with recommendations ranging from 3 to 5 days.[1,18,52] Steroids do increase surgical risk, particularly infectious, if an operation is required later.

(8) Patients, who are unresponsive to parenteral corticosteroids, have the option of receiving higher-potency agents such as cyclosporine or infliximab.[18,35] Among those unresponsive to corticosteroids, 76% to 85% will typically respond to IV cyclosporine.[64] Infliximab as a single 5 mg/kg IV dose or a continuous IV infusion of cyclosporine 2 to 4 mg/kg/day, with goal serum levels of 200-400 ng/mL (mcg/L), is the typical dose range utilized and may delay the need for colectomy.[1,18,35] Patients with ASUC who respond to infliximab should be continued on this agent, while those who are controlled on IV cyclosporine can be transitioned to maintenance therapy with azathioprine.

Maintenance of Remission

(9) After remission from active disease is achieved, the goal of therapy is to maintain remission for as long as possible. Various agents can be used and the choice may depend on the initial response to treatment, patient specific factors, and safety.

For patients with previously mildly active extensive or left side disease the oral aminosalicylate agents are preferred for maintenance therapy at a dose of at least 2 g/day.[18] The newer mesalamine derivatives are generally better tolerated than sulfasalazine and are associated with fewer adverse effects, making them a preferred choice.[1,18] For patients with proctitis, mesalamine suppositories are preferred at a dose of 1 g/day.[1,18,48,49] The frequency of administration of topical agents may be lessened to every third night over time.[1,18,48,49] For patients with previously moderate-to-severe active disease, the aminosalicylate products can be continued if remission is achieved initially with an aminosalicylate agent; however, the likelihood of sustaining remission is significantly lower, especially if more severe disease is present. Thiopurine monotherapy is recommended for maintenance in the setting of corticosteroid induced remission for moderate-to-severe disease.[18,35]

Corticosteroids have no role in the maintenance of remission, as they are ineffective and are associated with serious adverse effects with long-term use.[1,18,35,52] Budesonide oral MMX may be continued for up to 8 weeks for patients with moderate disease; however, systemic corticosteroids should be tapered over 4-12 weeks in moderately active UC patients achieving remission.[18,35,52] For patients who are steroid dependent, there is a strong justification for use of alternative therapies to allow for steroid withdrawal. Azathioprine may be effective in preventing relapse of UC for patients who fail ASAs or who are steroid dependent.[52-54] Approximately one-third of patients will maintain remission on azathioprine; however, the onset of action is slow and 3 to 6 months may be required before beneficial effects are noted.[52-54]

The TNF-α inhibitors, vedolizumab, ustekinumab, or tofacitinib are all options for maintenance in patients with moderate-to-severe UC following successful induction of remission, and in those who are steroid dependent or have failed azathioprine. Once patients with moderate-to-severe disease achieve remission with a biologic therapy or azathioprine there is no further role for aminosalicylate agents, so these should be discontinued.[35] For patients with ASUC, if remission with infliximab is achieved, this agent can be continued as maintenance therapy, while azathioprine or vedolizumab are recommended as maintenance therapies in patients achieving remission with cyclosporine.[35]

Crohn's Disease

Management of CD often proves more difficult than management of UC because of the greater complexity of presentation and the aggressive nature of the disease (Fig. 52-2; see Table 52-3). There is a greater potential for reliance on drug therapy with CD because resection of involved areas of the GI tract may not be possible. Surgical intervention is often required with rates of recurrence of CD following surgery reported in up to 80% of patients.[10]

Drug treatment of CD involves many of the same agents used for UC. While the treatment strategy for CD has often followed a similar "step-up" pattern as seen with UC, there has been more interest in the Treat-to-Target approach in patients with severe disease, which often involves more of a "step-down" approach of using more effective agents earlier in the disease course.[10,27,40]

Mild-to-Moderate Active Crohn's Disease

While effective in UC, ASAs have not demonstrated significant efficacy in CD. Sulfasalazine is reported to have marginal efficacy when compared with placebo for patients with mild-to-moderate CD, while the newer mesalamine derivatives are generally considered to have minimal efficacy.[27] Despite limited and variable effectiveness, the mesalamine derivatives are often tried as an initial therapy for mild-to-moderate CD in low-risk patients given their more favorable adverse effect profile.[67] Since CD often involves the small intestine, formulations such as Pentasa, which release in the small intestine, may be used to target areas of inflammation.

Systemic corticosteroids are frequently used for the treatment of moderate-to-severe active CD; however, controlled-release budesonide (Entocort) at a dose of 9 mg daily is a preferred first-line option for patients with mild-to-moderate ileal or right-sided (ascending colonic) disease.[27,52] This agent is superior to placebo and has demonstrated superiority to mesalamine and is preferred for patients with ileal disease.[27,52,67]

Antibiotics have little to no efficacy in treating luminal CD and are not recommended.[6,7,27] Broad-spectrum agents may be used for treatment of abscess formation in CD.[34] Metronidazole may have some role in prevention of postoperative recurrence of CD, and is also recommended for use in patients with perianal fistulas, particularly in combination with infliximab.[27]

Moderate-to-Severe Active Crohn's Disease

Patients with moderate-to-severe active CD require rapid suppression of inflammation for symptom improvement and prevention of complications. Oral corticosteroids, such as prednisone 40 to 60 mg/day, are generally considered first-line therapies for moderate-to-severe active CD who are unresponsive to ASAs.[10,27,52,60] Traditional oral systemic steroids have greater efficacy in inducing remission compared with budesonide in patients with moderate disease; however, the potential for adverse effects is greater, even with short-term use.[10,27,52] Hospitalized patients with moderate-to-severe disease who are unable to tolerate oral therapy are candidates for administration of parenteral steroids, with methylprednisolone or hydrocortisone being first-line options.[10,27] Systemic steroids do not appear to be effective for treatment of perianal fistulas, nor do they induce mucosal healing.[27,58]

⑩ Azathioprine, mercaptopurine, and methotrexate are generally not recommended for induction of remission as monotherapy in moderate-to-severe CD.[6,7,10,27] These agents are largely used for maintenance of remission, and are effective in maintaining steroid-induced remission and reducing steroid dependency, either as monotherapy or in combination with TNF-α inhibitors or vedolizumab.[10,27,53,54] Clinical response to azathioprine and mercaptopurine may be related to whole-blood concentrations of the metabolite 6-thioguanine (TGN). Concentrations of TGN between 230 and 450 pmol/8 × 10^8 erythrocytes have beneficial effects when used as monotherapy, but monitoring is not routinely performed or may not be available at some sites.[54,68]

⑪ Methotrexate given weekly intramuscularly or subcutaneously in doses of 15 to 25 mg is effective in reducing steroid dependency and maintaining remission, and may be considered as an alternative to azathioprine or mercaptopurine.[27]

The TNF-α inhibitors, including the biosimilar agents, are the preferred agents in the management of moderate-to-severe CD, especially those with high-risk features.[27,55,60,67] All agents in this class, with the exception of golimumab, which is not approved for use in CD in the United States, have similar rates of efficacy. The choice of agent depends on patient preference, route of administration, and cost. Adalimumab and certolizumab have the advantage of subcutaneous administration and may be considered alternates to infliximab as initial therapy or in those patients losing response to infliximab. Collectively these agents have demonstrated higher likelihood of induction of remission, reductions in hospitalization and the need for surgery, and lower rates of endoscopic recurrence.[10,27,57,58,60,67]

The use of TNF-α inhibitors in combination with thiopurines has quickly become the preferred approach to treatment of moderate-to-severe CD. Combination therapy results in added efficacy and reduction in antibody formation to the TNF-α inhibitor, which extends the duration of efficacy. Studies comparing infliximab to azathioprine combined with infliximab demonstrate greater rates of remission, steroid-free remission, and mucosal healing.[10,27,58] For this reason combination therapy is preferred unless patients have contraindications.

The integrin antagonists are options for patients who do not respond to steroids or have lost efficacy to or are intolerant of TNF-α inhibitors. Vedolizumab is also considered a first-line alternative to TNF-α inhibitors for moderate-to-severe disease.[27,59,60] These agents should not be used in combination with TNF-α inhibitors, but may be used with immunomodulators, which will also result in lower rates of antibody development.[27] Vedolizumab is preferred over natalizumab due to the reduced risk of adverse effects, particularly progressive multifocal leukoencephalopathy (PML) and has similar efficacy and safety outcomes compared to anti–TNF-α therapies.[59,60,69] If natalizumab is used, a baseline John Cunningham (JC) virus antibody must be negative prior to initiating therapy, and then should be monitored every 6 months. Therapy should be discontinued if a positive JC virus antibody is detected.[27]

Ustekinumab can be considered for moderate-to-severe CD in patients who have failed previous treatment with corticosteroids, immunomodulators, or TNF-α inhibitors, in patients with no prior exposure to TNF-α inhibitors.[27] This agent may be a preferred option for patients at higher risk of infections, those with advance age or multiple comorbidities, or in patients with prior malignancies.[27,56,60,62,67]

Severe/Fulminant Active Disease

Patients with severe or fulminant disease require prompt management in the inpatient setting and are often considered for surgical intervention. Parenteral corticosteroids at a dose equivalent of 40 to 60 mg prednisone should be instituted once the presence of abscess has been excluded.[27] TNF-α inhibitors may be used in severe disease, and infliximab may be considered in fulminant disease.[27] There are no data to support the use of cyclosporine, tacrolimus, or mycophenolate in patients with severe or fulminant disease.[27] TNF-α inhibitors are also considered first-line agents for fistulizing disease, with azathioprine and mercaptopurines as alternatives.[27] Patients may require surgical intervention in the setting of medically refractory disease.

Maintenance of Remission

Maintaining remission is typically more difficult with CD than with UC. Sulfasalazine may be considered in low-risk patients with disease confined to the colon who initially respond.[66] There is minimal evidence that oral mesalamine derivatives are effective therapies for maintenance of CD following medically induced remission, and therefore these agents are not preferred.[27,70] Mesalamine appears to have limited efficacy in preventing postsurgical relapse following resection, but can be considered in patients with isolated ileal resection with no risk factors for recurrence.[27] Metronidazole, 1 to 2 g/day, may also be used to prevent postoperative recurrence, but is not recommended for use in medically induced remission.[27]

Systemic corticosteroids have no role in maintenance of remission or prevention of recurrence of CD. These agents do not alter the long-term course of the disease and predispose patients to serious adverse effects with long-term use.[27] Despite a lower potential for systemic adverse effects, use of budesonide as maintenance therapy is only recommended for a duration of up to 4 months.[27]

All of the TNF-α inhibitors currently approved for use in CD are viable options for maintenance of remission.[27] Combination therapy with a thiopurine should be highly considered to further improve efficacy and to extend the duration of TNF-α inhibitor efficacy by reducing the immunogencity.[27] If surgical resection is being considered, TNF-α inhibitors should be started within 4 weeks of surgery in high-risk patients (age 2 prior resections for penetrating disease) in order to prevent postoperative recurrence.[71] Methotrexate may be considered as an alternative to thiopurines to maintain corticosteroid-induced remission.[27] Vedolizumab, natalizumab, and ustekinumab can be used for maintenance in patients who initially achieve induction of remission with these agents.[34]

Selected Complications

Toxic Megacolon

The treatment required for toxic megacolon includes general supportive therapy, consideration for early surgical intervention, and drug therapy.[24] Perforation can significantly worsen outcomes, with up to 44% of patients requiring surgery.[24] Aggressive fluid and electrolyte management is required for dehydration. Transfusion may be necessary if significant blood loss has occurred. Opiates and medications with anticholinergic properties should be discontinued because these agents enhance colonic dilation, thereby increasing the risk of bowel perforation. Broad-spectrum antimicrobials that include coverage for gram-negative bacilli and intestinal anaerobes should be used as preemptive therapy in the event that perforation occurs. If the patient is not receiving corticosteroids, then high-dose IV therapy with hydrocortisone 100 mg every 6 to 8 hours should be administered to reduce acute inflammation.[24] Emergent surgical intervention, mainly an abdominal colectomy with formation of an ileostomy, is an important consideration for patients with toxic megacolon and prevents death in some patients.[43-45]

Extraintestinal Manifestations

For some extraintestinal manifestations of IBD, specific therapies can be instituted, whereas for others the treatment that is used for the GI inflammatory process also addresses the systemic manifestations.

Anemia secondary to blood loss from the GI tract can be treated with oral ferrous sulfate. If the patient is unable to take oral medication and the patient's hematocrit is sufficiently low, blood transfusions or IV iron infusions may be required.[32] Anemia may also be related to malabsorption of vitamin B_{12} or folic acid, particularly for patients who have had ileal resection, so supplementation may be required.[28,29] Screening for osteoporosis does not differ significantly from the general population. Patients with conventional risk factors for abnormal bone density should be screened for osteoporosis with dual x-ray absorptiometry and then periodically thereafter.[72] Screening should also occur in patients starting oral corticosteroids, particularly in patients who have received greater than 7.5 mg/day equivalent of prednisone for longer than three consecutive months.[72] If the patient is deemed high risk for osteoporosis, such as those receiving corticosteroids, or exhibits a reduced serum vitamin D concentration, vitamin D supplementation should be instituted.[29] If osteoporosis is present, then calcium, vitamin D, and a bisphosphonate or possibly teriparatide are recommended.[32] Corticosteroid use should be avoided or limited, and weight-bearing exercise initiated if possible.

There are no consistently recommended therapies for aphthous ulcers; however, topical viscous lidocaine may provide symptom relief while topical corticosteroids may promote healing.[32] Episcleritis or uveitis is often worse during exacerbations of the intestinal disease, and measures improving intestinal disease will improve these systemic manifestations. Cool compresses and topical corticosteroids or NSAIDs may provide symptomatic relief, while immunomodulators and TNF-α inhibitors when in use may also provide benefit.[32] For arthritis associated with IBD, short-term NSAID or corticosteroids may be considered. However, NSAID use may exacerbate the underlying IBD and predispose patients to GI bleeding, so COX-2 inhibitors may be considered.[33,73] Intra-articular corticosteroids may be tried to limit the adverse effects of systemically administered agents.[32] Skin manifestations often require local wound care and use of topical or systemic corticosteroids.[32,33] Anti–TNF-α therapies may also improve severe dermatologic manifestations.

Adverse Drug Effects

Compared with mesalamine, sulfasalazine is more often associated with adverse drug effects, and these effects may be classified as either dose related or idiosyncratic (Table 51-4).[18,27,46,47,74] The sulfapyridine portion of the sulfasalazine molecule is believed to be responsible for much of the sulfasalazine toxicity.[18] Dose-related side effects usually include GI disturbances such as nausea, vomiting, diarrhea, or anorexia but may also include headache and arthralgia. These adverse reactions tend to occur more commonly on initiation of therapy and decrease in frequency as therapy is continued. Approaches to the management of these adverse effects include discontinuing the agent for a short period and then reinstituting therapy at a reduced dosage with subsequent slower dose escalation, administration with food, or substituting another enteric-coated 5-ASA product. Folic acid absorption is impaired by sulfasalazine, which may lead to anemia, so oral folic acid supplementation should be administered.

Idiosyncratic effects commonly include rash, fever, or hepatotoxicity, as well as relatively uncommon but serious reactions such as bone marrow suppression, thrombocytopenia, pancreatitis, pneumonitis, interstitial nephritis, and hepatitis. For most patients with idiosyncratic reactions, sulfasalazine must be discontinued. Mesalamine has been associated with development of interstitial nephritis as well, therefore intermittent monitoring of serum creatinine is warranted.[74]

Up to 80% of patients who are intolerant to sulfasalazine will tolerate oral mesalamine derivatives.[18] The most commonly encountered adverse effects are nausea, vomiting, and headache. However, olsalazine may cause watery diarrhea in up to 25% of patients, often requiring drug discontinuation.

Adverse effects of corticosteroids include hyperglycemia, hypertension, osteoporosis, acne, fluid retention, electrolyte disturbances, myopathies, muscle wasting, increased appetite, psychosis, infection, and adrenocortical suppression.[18,52,74] To minimize corticosteroid effects, clinicians may use alternate-day steroid therapy; however, some patients do not do well clinically on the days when no steroid is given. For most patients a single daily corticosteroid dose suffices, and divided daily doses are unnecessary. Adrenal insufficiency after abrupt steroid withdrawal often necessitates gradual tapering of steroid therapy for patients using these agents daily for more than 2 to 3 weeks. Budesonide is preferred in CD involving the ileum or right colon, or in UC, and may also be substituted for prednisone in CD patients who are steroid dependent or require long-term therapy.[27,60]

Azathioprine and mercaptopurine may be associated with serious adverse effects such as lymphomas, pancreatitis, or nephrotoxicity.[18,27,53,54,74] Adverse events to thiopurines are typically divided into two groups: type A and type B.[27,35,54] Type A reactions are dose related and include malaise, nausea, infectious complications, hepatitis, and myelosuppression. Complete blood counts with differential should be monitored every 2 weeks while doses are being titrated. Type B reactions are considered idiosyncratic and include fever, rash, arthralgia, and pancreatitis (3%-15% of patients).[35,53,54] Predisposition to development of these adverse effects may be related to polymorphisms in the enzyme thiopurine methyltransferase (TPMT), which is partially responsible for activation and metabolism of these drugs. Determination of TPMT activity is recommended prior to initiation of therapy to determine which patients require lower doses of these agents.[54,74,75] Alternatively, evaluating TPMT genotype or phenotype can also assist in assessing a patient's risk for toxicity.[61,62,74,75] Doses may need to be reduced by 30% to 80% if low TPMT activity is present.[75] Adjusting azathioprine and mercaptopurine doses by measuring concentrations of metabolites, particularly TGN, may be useful, with target concentrations of 230 to 450 pmol/8 x 10^8 erythrocytes considered optimal.[61,62,68,75-77]

Variations in the NUDT15 allele also predisposes patients using mercaptopurine to excess myelosuppresion.[75,76] Assessment of the NUDT15 phenotype can be performed as well if Mercaptopurine is used, with similar recommendations for dose reductions if poor or intermediate metabolizer status is present.[75] Since the initial dosing of these agents is weight based, obtaining a current accurate weight for the patient is necessary as well. Obtaining a family history regarding lymphoproliferative disorders or lymphoma is important for determining if the potential risks outweigh the benefits of long-term use. Women receiving immunosuppressive therapy should undergo annual cervical cancer screening and all patients should be screened annually for melanoma.[72]

With the advent of coadministration of azathioprine with infliximab, development of hepatosplenic T-cell lymphoma (HSTCL) has become a concern. The overall impact of using both drugs together, the contribution of drug classes to the development of lymphoma, and the risk and effects of both drugs are unclear. Those most at risk appear to be younger male patients (<35 years) and most of the risk is thought to be conferred by the thiopurine component.[53,74] Thiopurines are also associated with the development of non-melanoma squamous cell carcinoma, with the risk being higher during combination therapy with TNF-α inhibitors.[72,74] Methotrexate is associated with the development of nausea, vomiting, pulmonary fibrosis, pneumonitis, hepatotoxicity, anemia, and renal dysfunction, and is a known abortifacient. Patients should have baseline liver function tests, serum creatinine, BUN, complete blood count, and chest x-ray prior to use. Female patients should have a negative pregnancy test prior to use. Some patients may require supplementation with folic acid. Female patients of childbearing age opting to use methotrexate should have a safe and effective method of birth control available that is based on their preference.

Most patients receiving metronidazole for CD tolerate the agent fairly well; however, mild adverse effects occur frequently. They commonly include nausea, metallic taste, urticaria, and glossitis.[27,74] More serious effects that occur with long-term use include development of paresthesias and reversible peripheral neuropathy. Other effects include a disulfiram-like reaction if alcohol is ingested in conjunction.

The TNF-α inhibitors may be associated with development of serious adverse effects and carry similar adverse effect profiles for the available agents. Patients who receive infliximab often develop antibodies to infliximab (ATIs), also referred to as antidrug antibodies (ADAs). These ADAs can develop in response to administration of the other TNF-α inhibitors as well. Overall up to 50% of patients may lose efficacy after 1 year of treatment due to ADA development.[68] The development of ADAs also results in increases in the occurrence of serious infusion-related reactions in up to 2.8% of patients.[75] Up to 10% of patients per year require discontinuation of infliximab due to adverse effects and loss of efficacy related to development of ATIs.[55,58,74,76]

Strategies to reduce ATI formation include administration of a second dose within 8 weeks of the first dose, concurrent administration of steroids (hydrocortisone 200 mg IV on the day of the infusion or oral prednisone the day prior), and use of concomitant immunomodulators agents such as thiopurines.[18,27,58,74] Loss of efficacy may be managed by a dose escalation to 10 mg/kg, reducing the dosing interval, or switching to another TNF-α inhibitor.[27,55,74,77] Delayed hypersensitivity reactions may also occur up to 14 days after administration, with 5 to 7 days being the most common time frame. Autoimmune phenomena, such as lupus and hemolytic anemia, may also occur during infliximab therapy but are uncommon, as are adverse neurologic events such as optic neuritis and demyelinating syndrome.[74,76] Anti-TNF agents may also cause worsening of heart failure and should be avoided in patients with New York Heart Association Class III or IV heart failure.

All TNF-α inhibitors predispose patients to development of serious infections, including fungal, bacterial, and viral. Patients with clinically significant active infections should not receive TNF-α inhibitors. While the overall risk of hospitalization for serious infections may be less than previously suspected, development of infection remains a serious concern and increases with age.[67,74,76] Reactivation of latent mycobacterial infections may occur because of the inhibition of TNF-protective mechanisms; therefore, patients should receive a tuberculin skin test (purified protein derivative [PPD] test) and a chest x-ray prior to initiating therapy to rule out undiagnosed tuberculosis.[67,74,76] Reactivation of hepatitis B may occur; thus, patients should also be screened for hepatitis B virus infection prior to initiating therapy. Patients should also be screened for hepatitis C infection, although it does not appear that use of TNF-α inhibitors is unsafe or significantly alters the disease course. Natalizumab is associated with development of PML and is only available via the manufacturer's TOUCH prescribing program. Patients receiving natalizumab should be monitored for development of adverse neurologic events and undergo MRI of the brain should development of PML be suspected. Vedolizumab has not been associated with development of PML and may be associated with a lower risk of infection compared to TNF-α inhibitors.[69,74,76] Ustekinumab and tofacitinib carry many of the same adverse effect profile as the TNF-α inhibitors, and baseline screening for TB and hepatitis should be performed; however, overall risk of serious infection appears to be lower compared to TNF-α inhibitors.[67,69,74,76] Tofacitinib is also associated with development of thrombosis and lymphoma, as well as neutropenia, lymphopenia, and anemia.[60,63,74,76] The risk of thrombosis was observed at the higher doses of 10 mg twice daily, and in trials of patients with rheumatoid those greater than 50 years of age with at least one cardiovascular risk factor were at higher risk.[78] Tofacitinib should be avoided in patients with risks for thrombosis or history of pulmonary, deep vein, or arterial thrombosis.[78] Ozanimod is associated with the development of several potentially serious adverse effects. These include increased rate of infection, macular edema, fetal abnormalities, bradycardia or atrioventricular block, liver injury, and respiratory dysfunction. This necessitates a thorough patient history be obtained for presence of cardiovascular or cerebrovascular events within the last 6 months, as well as a history of sleep apnea.

For patients receiving ustekinumab and tofacitinib, baseline screening for latent infections should be performed. If patients appear to be losing response to TNF-α inhibitors, evaluating for ADAs, if assays are available, in addition to evaluating serum trough concentrations may assist the clinician in determining if dose and frequency need to be altered. Recommendation trough concentrations for TNF-α inhibitors include >5 μg/mL (mg/L) for infliximab, >7.5 μg/mL (mg/L) for adalimumab, >20 μg/mL (mg/L) for certolizumab, while optimal concentrations for golimumab are unknown.[68]

Patients should be evaluated for use of recommended vaccines; however, if patients are receiving immunosuppressants or biologic agents, the use of live or attenuated vaccines may be contraindicated.[72] Patients who currently use tobacco should be encouraged to undergo tobacco cessation, as tobacco use will worsen CD.[27,72] Since nicotine often improves symptoms in UC, it may be more difficult to cease tobacco use in this patient population. Choice of tobacco cessation products should also be based on current nicotine consumption and patient preference.

Special Considerations

Pregnancy and Breastfeeding

The occurrence or consideration of pregnancy may cause significant concerns for the patient with IBD. Patients with IBD have similar infertility rates as the general female population, and the rate of involuntary childlessness in IBD patients who have not undergone surgery is similar.[79-81] There is a greater risk of adverse pregnancy outcomes such as spontaneous abortion, low birth weight, cesarean section, congenital abnormalities, low Apgar scores, preterm rupture of membranes, and preeclampsia.[79-81] However, most patients can conceive normally and have a normal pregnancy. The impact of IBD disease activity on pregnancy still remains unclear. In patients in remission at the time of conception the rates of reported flares are 20% in CD and 33% in UC, and postpartum rates of relapse are reported as 14%.[78-81] Preconception counseling in patients with IBD is recommended, in addition to objective assessment of disease activity in order to optimize therapy.[1,8] Overall patients should optimally achieve at least 3 to 6 months of corticosteroid-free remission prior to conceiving.[7,9] Patients should be managed by a gastroenterologist throughout their pregnancy, and also be referred to an obstetrician who manages high-risk patients if they have active or complicated disease.[80,81]

Diligence should be given to reviewing current medications in patients with IBD who are both contemplating pregnancy or have already conceived. Sulfasalazine is generally well tolerated; however, it does interfere with folate absorption, so supplementation with folic acid 1 mg twice daily should be used during the pregnancy.[74,79,80] Sulfasalazine causes decreased sperm counts and reduced fertility in males and corticosteroids may adversely affect fertility as well.[82] This effect is reversible on discontinuation of the drug, and it is not reported with mesalamine. Other ASAs can be used as well; however, there are concerns regarding the presence of dibutyl phthalate in the coating of Asacol.[7,9] Mesalamine preparations not containing dibutyl phthalate should be preferentially used.[7,80] Steroids given systemically do not appear to be detrimental to the fetus, and in general can be used in the same manner as in non-pregnant patients.[4,7,8,80] Due to its lower systemic bioavailability budesonide may be considered safer than other systemic corticosteroids for pregnant patients.[4,7] Azathioprine and mercaptopurine appear to carry an overall minimal risk in pregnant patients, and should be continued in patients receiving these agents as maintenance therapy.[74,80] Given pharmacokinetic changes in azathioprine metabolism occur during pregnancy, monitoring of 6-TGN during and after pregnancy is indicated.[80] Use of TNF-α inhibitors in pregnant patients appear to carry an overall low risk, and continuation of therapy is warranted in most patients. Infliximab, adalimumab, and golimumab do cross the placenta and there are some concerns with increased exposure to the fetus in the third trimester. While the risk is low, consideration can be given to administering the last dose at 22 to 24 weeks of gestation to minimize drug transfer to the fetus in patients considered low risk for relapse.[75,80,81] For newborns of women who were receiving TNF-α inhibitors during pregnancy it is recommended that use of live vaccines be avoided.[80] In patients receiving combination therapy with azathioprine and a TNF-α inhibitor, consideration of switching to monotherapy can be given, with use of a TNF-α inhibitor as preferred therapy.[80] Natalizumab, vedolizumab, and ustekinumab appear to carry low risk when used as monotherapies; however, consideration can also be given to administering the last dose at 8 to 10 weeks prior to delivery to minimize fetal exposure.[7,9] Tofacitinib does not appear to cause birth defects, miscarriage, or adverse fetal outcomes. There is a pregnancy registry that women who become pregnant while receiving tofacitinib are encouraged to enroll in. Metronidazole and ciprofloxacin may be used for short courses for treatment of perianal disease, and should be avoided during the first trimester if possible.[74,79,81] Methotrexate should not be used during pregnancy, and should be stopped 3 months prior to conception. It should be stopped immediately in patients who become pregnant while taking it, with referral for obstetric counseling.[1,8]

Use of agents in breastfeeding women is also a consideration. Sulfasalazine does pose a small risk of kernicterus, as levels of sulfapyridine in breast milk are low or undetectable, and thus monitoring for this symptom should be implemented.[79-81] Other mesalamine derivatives are considered safe in breastfeeding.[78,79] Corticosteroids can be detected in breast milk, with fetal levels approximately 10% to 12% of maternal levels.[79] However, breastfeeding is believed to be safe, but mothers should optimally wait at least 4 hours after an oral dose of systemic corticosteroids before breastfeeding to limit exposure to the child.[7,9] The anti–TNF-α agents and thiopurines are generally considered safe for use in breastfeeding and carry minimal risk of adverse effects.[74,81] Methotrexate should be avoided in breastfeeding mothers.[1,8] Metronidazole and cyclosporine should not be given to nursing mothers because these agents are excreted into breast milk and may cause adverse effects.[74,78-81]

Children and Adolescents

IBD can present early in life, with 6% to 15% of patients being diagnosed prior to 6 years of age, and CD being more prevalent than UC.[83,84] This distinction in pediatric patients is referred to as very-early-onset IBD (VEO-IBD).[83] Due to the aggressive nature of CD, patients may be at risk for poor nutritional status, growth failure, micronutrient deficiencies, anemia, and pubertal delay.[84,85] Patients should be assessed for nutrient deficiencies, particularly iron and vitamin D, and replacement implemented if needed.[83-87]

Drug treatment in pediatric patients is similar to adults, with mesalamine, azathioprine, and the TNF-α inhibitors all being viable options. Due to the association with development of lymphoma and pharmacokinetic changes in metabolism as patients get older, thiopurines are used less often in pediatric patients.[83] Due to the potential for adverse effects, corticosteroid use should be limited to short-term use as induction therapy. The TNF-α inhibitors have become a major drug class used in the management of pediatric patients with IBD for both induction and maintenance of remission. Infliximab is approved for use in the United States for patients 6-17 years of age with moderate-to-severe active CD. Adalimumab is also approved for use in patients 6 years of age or older with CD. Studies indicate that early use significantly improves clinical outcomes, such as remission and mucosal healing.[88] However, initial response rates in patients to infliximab with VEO-IBD may actually be lower due to differences in pharmacokinetics and immune pathways of the disease.[83] This may necessitate higher and more frequent dosing to optimize therapy. Data are lacking to support routine use of vedolizumab, ustekinumab, and tofacitinib in pediatric patients.

Older Adults

Up to 30% of patients with IBD develop symptoms after age 60, and prevalence in older patients appears to be increasing.[89,90] In North America the incidence of IBD is reported as 4-8 per 100,000 persons greater than age 60 and 15% of cases are diagnosed after age 60.[90] One of the difficulties in diagnosis of IBD is that patients greater than 60 years of age may have other conditions present that may mimic IBD symptoms. This includes ischemic colitis, diverticular disease, microscopic colitis, CRC, NSAID-induced intestinal changes, or radiation induced enteritis or colitis.[89,90] Older patients with CD may present more often with isolated colonic disease, while left-sided disease is more common in elderly patients with UC.[90]

The approach to drug therapy in older adults is similar to younger individuals; however, a multidisciplinary approach is favored given the greater number of comorbidities and medications that may be present.[90] Overall patient fitness and frailty should be assessed, as this may impact the potential for serious adverse effects from medications, such as infection.[89,90] The aminosalicylates can be used for both induction and maintenance therapy; however, routine monitoring of renal function should be implemented, as interstitial nephritis is a potential adverse effect.[90] Corticosteroids should still be reserved for short courses as induction therapy, as older patients may have conditions that corticosteroids may worsen, such as diabetes, hypertension, heart failure, glaucoma, or osteoporosis.[89,90] Budesonide may be preferred, if possible, due to the lower systemic bioavailability.

Thiopurines are an attractive option due to their oral route of administration, however there are concerns about increases in hepatotoxicity and nonmelanoma skin cancers in older patients.[90,91] They should be used cautiously in this population, and methotrexate may be an alternative in some instances.[90,91] The TNF-α inhibitors can be used for induction and maintenance; however, more frail patients may be at higher risk for infection and malignancy, especially if used in combination with a thiopurine. Combination therapy should be reserved for patients with severe disease.[90] Use of ustekinumab or vedolizumab may be preferred for more frail patients due to the lower overall risk for infection.[74,76,90] Tofacinib is largely reserved as a second-line agent in elderly patients, due to both lack of data and increases in risk of thromboembolic disease. Lastly, older patients with IBD should have routine health screening and maintenance performed. This is important in this patient population due to the need for maintaining appropriate vaccinations and implementing screenings for osteoporosis and CRC.[72,92]

PATENTS WITH COVID-19 INFECTION

Given that patients with IBD are often receiving one or more immunosuppressive agents, concerns with the COVID-19 pandemic were that patients would be at higher risk for infection and potentially worse outcomes. In order to communicate information rapidly, an international reporting website, https://covidibd.org/, was formed to allow clinicians and investigators to report outcomes related to COVID infection in both adult and pediatric patients with IBD. This resulted in an initial report of outcomes in over 500 patients in 33 countries.[93] Based on the analysis, patients with IBD who were older, had multiple comorbidities, or were receiving corticosteroids had more severe COVID-19 disease. Interestingly, TNF-α use was not associated with severe COVID-19 disease. A subsequent meta-analysis demonstrated that the risk of acquiring COVID-19 in patients with IBD is not significantly different than the general population and does also not differ based on subtype of IBD.[93] Worse outcomes, such as hospitalization and increased mortality was seen more in patients with UC and in patients receiving 5-ASA products or corticosteroids. TNF-α use was actually found to be a protective factor in this trial, indicating that the anti-inflammatory effects of these drugs may actually attenuate some aspects of COVID-induced inflammation. With regard to the COVID-19 vaccines, the Crohns and Colitis Foundation have released recommendations that patients with IBD should receive the vaccine, regardless of current medication use (https://www.crohnscolitisfoundation.org/coronavirus/vaccines). Both international and British guidelines also advocate for the same approach, indicating that the benefit of vaccination as soon as possible in patients with IBD outweighs the risk of potential reduced response in those receiving immunosuppressive therapies.[94-96]

EVALUATION OF THERAPEUTIC OUTCOMES

The success of therapeutic regimens to treat IBD can be measured by patient-reported complaints, signs, and symptoms; by direct clinician examination (including endoscopy); by history and physical examination; by selected laboratory tests; and by QOL measures. Evaluation of IBD severity is difficult because much of the assessment is subjective. Disease rating scales, such as the CDAI or other indices, have been created to make disease assessment more objective. The CDAI is a commonly used scale for patients with nonfistulizing disease and for evaluation of patients during clinical trials.[10,27] The scale incorporates eight elements: (a) number of stools in the past 7 days, (b) sum of abdominal pain ratings from the past 7 days, (c) rating of general well-being in the past 7 days, (d) use of antidiarrheals, (e) body weight, (f) hematocrit, (g) finding of abdominal mass, and (h) a sum of extraintestinal symptoms present in the past week. Elements of this index provide a guide for those measures that may be useful in assessing the effectiveness of treatment regimens. A decrease in CDAI of 100 points is considered a clinically significant response, with a score of less than 150 considered to be disease remission.[10,27] A subsequent scale was developed specifically for perianal CD, known as the *Perianal Crohn's Disease Activity Index* (PDAI). The PDAI includes five items: presence of discharge, pain, restriction of sexual activity, type of perianal disease, and degree of induration. The HBI may also be used in place of the CDAI.

Standardized assessment tools have also been constructed for UC.[1,18] Elements in these scales vary and include (a) stool frequency, (b) presence of blood in the stool, (c) mucosal appearance (from endoscopy), and (d) physician's global assessment based on physical examination, endoscopy, and laboratory data. While these tools are often used for assessment of patients in clinical trials, they are sometimes used in the clinical setting as well.

Additional studies that are often useful include direct endoscopic examination of affected areas and/or radiocontrast studies. Mucosal healing is considered a major end point for patients with luminal disease. For patients with acute disease, assessment of fluid and electrolyte status is important, because these may be lost during diarrheal episodes. Other laboratory tests, such as serum albumin, transferrin, or other markers of visceral protein status as well as markers of inflammation such as ESR or CRP, and fecal calprotectin, are used to monitor disease and drug therapy. Lastly assessing for both trough concentrations and presence of ADAs can help guide therapy in patients who are not responding to normal doses of TNF-α inhibitors.

Finally, a patient QOL assessment should be performed regularly.[1,18,27] Inquiry should be made regarding the patient's general well-being, emotional function, and social function. Social function may include assessment of the ability to perform routine daily functions and to maintain occupational activities, sexual function, and recreation. The most common tool used to assess QOL is the Inflammatory Bowel Disease Questionnaire (IBDQ), a 32-item questionnaire that covers four disease dimensions: bowel function, emotional status, systemic symptoms, and social function. The IBDQ has shown good correlation with the CDAI.[27] The standard short form 36 (SF-36) is often used as a measure of QOL in IBD intervention trials.

ABBREVIATIONS

ADA	antidrug antibody
ASA	aminosalicylate
ATI	antibody to infliximab
CD	Crohn's disease
CDAI	Crohn's Disease Activity Index
CRC	colorectal carcinoma
CRP	C-reactive protein

ESR	erythrocyte sedimentation rate
FC	fecal calprotectin
FODMAPS	fermentable oligo-, di-, and monosaccharides and polyols
HBI	Harvey-Bradshaw Index
HLA	human leukocyte antigen
HSTCL	hepatosplenic T-cell lymphoma
IBD	inflammatory bowel disease
IBDQ	Inflammatory Bowel Disease Questionnaire
IL	interleukin
IPAA	ileal pouch anal anastomosis
JAK	Janus Kinase
MMX	Multi-MatriX
NF-κ B	nuclear factor κ B
NOD2	nucleotide-binding oligomerization domain protein 2
NSAID	nonsteroidal anti-inflammatory drug
PDAI	perianal Crohn’s Disease Activity Index
PML	progressive multifocal leukoencephalopathy
PPD	purified protein derivative
PSC	primary sclerosing cholangitis
QOL	quality of life
SCD	specific carbohydrate diet
S1P	sphingosine-1 phosphate
TGF-*β*	transforming growth factor-*β*
TGN	thioguanine
TLR	toll-like membrane receptor
TNF-*α*	tumor necrosis factor-*α*

TPMT	thiopurine methyltransferase
UC	ulcerative colitis
VTE	venous thromboembolism

SELF-ASSESSMENT QUESTIONS

1. A patient with extensive ulcerative colitis has disease located:

    A. Only in the rectal area

   B. In the rectum and sigmoid colon
   C. In the terminal ileum
   D. Throughout the majority of the colon

2. In patients with ulcerative colitis symptoms may be worsened by which of the following factors?
   A. Use of ibuprofen
   B. Use of acetaminophen
   C. Nicotine use
   D. Exercise
3. Which enzyme's activity should be evaluated prior to initiation of therapy in patients receiving azathioprine?
   A. Xanthine oxidase
   B. CYP2D6
   C. TPMT
   D. HLA DRPHLA-DR2
4. Which of the following is more characteristic of ulcerative colitis versus Crohn's disease?
   A. Confinement of disease to the small intestine
   B. Fistula formation
   C. Involvement of the terminal ileum
   D. Superficial continuous inflammation of the intestinal mucosa
5. Which adverse effect may occur at a higher rate in patients receiving the combination of infliximab and azathioprine?
   A. Pancreatitis
   B. Lymphoma
   C. Hepatitis
   D. Encephalopathy
6. Which of the following drugs is administered intravenously?
   A. Golimumab
   B. Adalimumab
   C. Certolizumab
   D. Vedolizumab
7. Which location best describes the site of action of oral budesonide (Entocort EC)?
   A. Sigmoid colon

   B. Rectal area

   C. Terminal ileum

   D. Duodenum

8. Which one of the following is a potential adverse effect of ustekinumab?

   A. Risk of infection

   B. Progressive multifocal leukoencephalopathy

   C. Neural tube defects

   D. Heart failure

9. Antibody development to infliximab may result in:

   A. Increased trough concentrations

   B. Increase in duration of action

   C. Reduction in therapeutic efficacy

   D. Reduction in infusion related adverse events

10. Which drug is recommended for acute treatment of a hospitalized patient with fulminant Crohn's disease who has failed maximum doses of intravenous corticosteroids?

   A. Azathioprine

   B. Cyclosporine

   C. Budesonide

   D. Methotrexate

11. Which medication may induce infertility in male patients with inflammatory bowel disease?

   A. Mesalamine

   B. Sulfasalazine

   C. Certolizumab

   D. Golimumab

12. Which medication is associated with an increased risk of blood clots?

   A. Budesonide

   B. Tofacitinib

   C. Prednisone

   D. Ustekinumab

13. Which medication is most effective for treatment of mild-to-moderate proctitis in a patient with UC?

A. Sulfasalazine

B. Mesalamine suppository

C. Hydrocortisone enema

D. Ciprofloxacin

14. Which preventative measure is most appropriate for all patients with active IBD?

A. Annual influenza vaccination

B. Yearly colonoscopy

C. Thiamine supplementation

D. Folic acid supplementation

15. Which of the following is an extraintestinal manifestation of inflammatory bowel disease?

A. Pyoderma gangrenosum

B. Hypothyroidism

C. Hypertension

D. Glaucoma

SELF-ASSESSMENT QUESTION-ANSWERS

1. D. Disease affecting the entire colon is called extensive, while left-sided refers to involvement of the sigmoid colon and rectum. Disease confined just to the rectal area in patients with IBD is referred to as proctitis.

2. A. Use of NSAIDs may worsen symptoms in patients with IBD, as they disrupt the intestinal barrier. Acetaminophen is generally safe for patients with IBD. Nicotine use may actually improve symptoms in patients with UC, while exercise has no effect on disease symptoms.

3. C. Thiopurine methyltransferase (TPMT) is a key enzyme involved in the metabolism of azathioprine. Activity of TPMT should be evaluated prior to initiation of azathioprine to determine if alterations in the dose are required.

4. D. The depth of inflammation is shallower than that observed in CD. For this reason, inflammation may penetrate the intestinal wall and affect adjoining structures, resulting in fistula formation in patients with CD. The small intestine is often the most common site affected in CD, while the colon and rectal area are more commonly affected in patients with UC.

5. B. The combination of TND-α inhibitors and thiopurines may result in higher incidences of hepatosplenic T-cell lymphoma, although the majority of risk is thought to be due to thiopurine.

6. D. Vedolizumab requires intravenous administration, while golimumab, adalimumab, and certolizumab may be given subcutaneously.

7. C. Oral budesonide (Entocort EC) is formulated to deliver budesonide to the terminal ileum, which is the most commonly affected section of the GI tract in patients with CD.

8. A. Usetkinumab blocks the activity of IL-12 and IL-23, which predisposes patients to an increased risk of infection.

9. C. Development of antidrug antibodies to the TNF-α inhibitors may ultimately neutralize the drug, resulting in loss of efficacy over time and the potential for increases in infusion-related reactions.

10. B. Cyclosporine or infliximab is endorsed by the AGA guidelines as a treatment option for patients with fulminant CD who fail systemic corticosteroids.

11. B. Chronic use of sulfasalazine had been associated with reductions in sperm count in male patients, and thus may contribute to infertility.

12. B. Tofacitinib has been associated with increases in pulmonary, venous, and arterial thromboembolism and should be avoided in patients with a history of clots or those at risk.

13. B. Topical mesalamine (suppository) delivers higher concentrations to the site of inflammation, which for proctitis would be the most effective. This results in better efficacy than orally administered aminosalicylates. Topical corticosteroids are considered less effective than topical mesalamine.

14. A. Patients with IBD should receive the usual annually recommended vaccinations, such as influenza.

15. A. Extraintestinal manifestations of IBD can affect many different organ systems, with the skin being a commonly involved site. Both pyoderma gangrenosum and erythema nodosum can be encountered in patients with IBD.

Chapter 53: Nausea and Vomiting

Leigh Anne Hylton Gravatt; Krista L. Donohoe; Mandy L. Gatesman

KEY CONCEPTS

KEY CONCEPTS

① Nausea and/or vomiting is often a part of the symptom complex for a variety of gastrointestinal (GI), cardiovascular, infectious, neurologic, metabolic, or psychogenic processes.

② Nausea or vomiting is caused by a variety of medications or other noxious agents.

③ The overall goal of treatment should be to prevent or eliminate nausea and vomiting regardless of etiology.

④ Treatment options for nausea and vomiting include drug and nondrug modalities such as relaxation, biofeedback, and hypnosis.

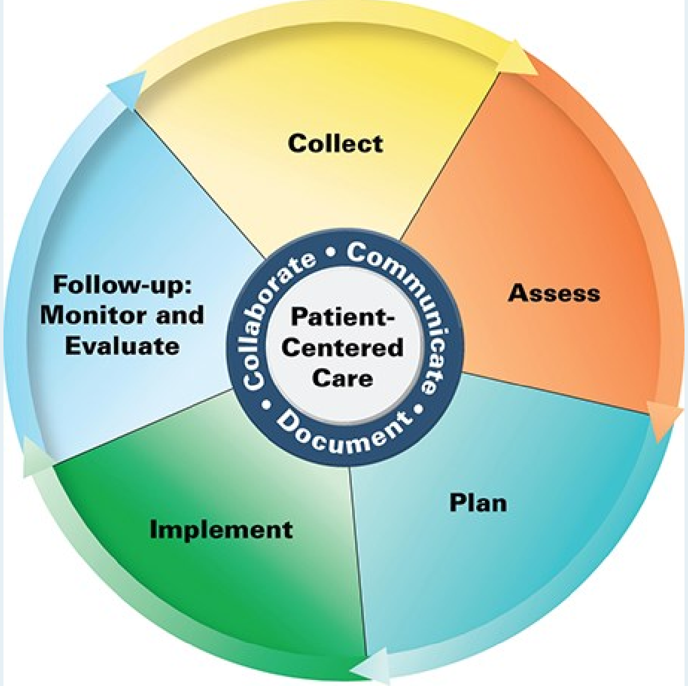
⑤ The primary goal with chemotherapy-induced nausea and vomiting (CINV) is to prevent nausea and vomiting throughout the entire risk period; the emetic risk of the chemotherapeutic regimen is a major factor to consider when selecting a prophylactic regimen.

⑥ Patients at high risk of vomiting should receive prophylactic antiemetics for postoperative nausea and vomiting (PONV).

⑦ Antihistaminic–anticholinergic agents are the most effective therapy for balance disorders.

PATIENT CARE PROCESS

Patient Care Process for Nausea and Vomiting



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnancy status, triggers)
- Patient medical history (personal and family), history of NV
- Social history (eg, tobacco/ethanol/cannabis use) and dietary habits
- Current medications including prescription and nonprescription medications, herbal products, dietary supplements
- Objective data (eg, QTc prolongation, BP/pulse, complete metabolic panel, CBC, liver function, weight, skin turgor, urine output)

Assess

- Duration, frequency, severity of nausea and vomiting
- Ability/willingness to pay for treatment options
- Emotional status (eg, presence of anxiety, depression)
- Assess ability of the patient to use oral, rectal, injectable, or transdermal medications
- Success of previous antiemetic regimens
- For CINV: Assess emetic risk of chemotherapy (see Table 53-7)
- For PONV: Assess risk factors for developing PONV (see Table 53-6)

Plan*

- Drug therapy regimen including specific antiemetic(s), dose, route, frequency, and duration (see Tables 53-4 and 53-7)
- Monitoring parameters including efficacy (eg, reduction in symptoms, resolution of lab abnormalities, resumption of normal oral intake) and safety (eg, QTc prolongation, drug-drug interactions); frequency and timing of follow-up

- Patient education (eg, purpose of treatment, dietary and lifestyle modification, invasive procedures, drug-specific information, medication administration technique)
- Self-monitoring for resolution of symptoms, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, gastroenterologist, dietitian, OBGYN, oncologist, anesthesiologist)

Implement[*]

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, adherence assessment

Follow-Up: Monitor and Evaluate

- Resolution of nausea and vomiting symptoms
- Need for rescue antiemetics
- Presence of adverse effects
- Patient adherence to treatment plan

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Drug Information Question: Can you use medical marijuana for nausea and vomiting in your state? Research your state laws and the evidence-based literature for using medical marijuana for nausea and vomiting.

INTRODUCTION

Nausea and vomiting are common complaints from individuals of all ages. Management can be simple or detailed and complex, depending on the etiology. This chapter provides an overview of nausea and vomiting, two multifaceted problems. Nausea is defined as the inclination to vomit or as a feeling in the throat or epigastric region alerting an individual that vomiting is imminent. Vomiting is the ejection or expulsion of gastric contents through the mouth and is often a forceful event. Either condition may occur transiently with no other associated signs or symptoms; however, these conditions may be part of a more complex clinical presentation.

ETIOLOGY

① Nausea and vomiting may be associated with a variety of conditions, including gastrointestinal (GI), cardiovascular, infectious, neurologic, or metabolic disease processes. Nausea and vomiting may be a feature of conditions such as pregnancy, or may follow operative procedures or administration of certain medications such as those used in treating cancer. Psychogenic etiologies of these symptoms may be present. Anticipatory etiologies may be involved, such as in patients who have experienced poor nausea and/or vomiting control with previous antineoplastic agents. Table 53-1 lists specific etiologies associated with nausea and vomiting.[1]

TABLE 53-1

Etiologies of Nausea and Vomiting

- **Intraperitoneal**
- Mechanical obstruction
- Gastric outlet obstruction
- Bowel obstruction
- Altered sensorimotor function
- Gastroparesis
- Gastroesophageal reflux
- Intestinal pseudo-obstruction
- Irritable bowel syndrome
- Chronic idiopathic nausea
- Functional vomiting
- Cyclic vomiting syndrome
- Cannabinoid hyperemesis syndrome
- Rumination syndrome
- Inflammatory diseases
- Pancreatitis
- Pyelonephritis
- Cholecystitis
- Appendicitis
- Hepatitis
- Acute gastroenteritis
- Viral
- Bacterial
- Biliary colic
- Liver failure

- **Cardiovascular diseases**
- Acute myocardial infarction
- Cardiomyopathy

- **Neurologic processes**
- Increased intracranial pressure
- Migraine headache
- Vestibular disorders
- Intracerebral hemorrhage
- Intracerebral malignancy

- **Metabolic disorders**
- Diabetes mellitus (diabetic ketoacidosis)
- Addison’s disease
- Renal disease (uremia)

- **Psychiatric causes**
- Depression
- Anxiety disorders

• Anorexia and bulimia nervosa
• **Therapy-induced causes** • Antineoplastic agents • Radiation therapy • Anticonvulsant preparations • Digoxin, Cardiac antiarrhythmics • Opiates • Oral hypoglycemics • Oral contraceptives • Antibiotics • Volatile general anesthetics • Lubiprostone
• **Drug withdrawal** • Opiates • Benzodiazepines
• **Miscellaneous causes** • Pregnancy • Noxious odors • Postoperative vomiting

Data from Reference [1].

The etiology of nausea and vomiting may vary with the age of the patient. For example, vomiting in the newborn during the first day of life suggests upper digestive tract obstruction or an increase in intracranial pressure.

② Nausea or vomiting is caused by a variety of medications or other noxious agents. Drug-induced nausea and vomiting is of particular concern, especially with the increasing number of patients receiving antineoplastic agents. A four-level classification system defines the risk for emesis with agents used in oncology (Table 53-2).[2] Although some agents may have greater emetic risk than others, combinations of agents, higher doses, clinical settings, psychological conditions, prior treatment experiences, and unusual stimulus of sight, smell, or taste may alter a patient's response to antiemetic treatment. In this setting, nausea and vomiting may be unavoidable and some patients experience these problems so intensely that chemotherapy is postponed or discontinued.

TABLE 53-2

Emetic Risk of Agents Used in Oncology and Treatment Options

Antiemetic Agent	Antiemetic Dose on Day 1 of Chemotherapy	Antiemetic Dose on Subsequent Days
High Risk (>90%): Anthracycline/Cyclophosphamide combination, Carmustine, Cisplatin, Cyclophosphamide >1,500 mg/m^2, Dacarbazine, Mechlorethamine, Streptozocin		
NK-1 Antagonist		
Aprepitant	125 mg oral or 130 mg IV	80 mg oral on days 2-3

Fosaprepitant	150 mg IV	
Netupitant-palonosetron	300 mg / 0.5 mg oral	
Fosnetupitant-palonosetron	235 mg fosnetupitant/0.25 mg palonosetron IV	
Rolapitant	180 mg oral	
5-HT$_3$ Antagonist[a]		
Granisetron	2 mg oral or 1 mg IV or 10 mcg/kg IV or 1 patch or 10 mg SQ	
Ondansetron	24 mg oral or 8 mg IV or 0.15 mg/kg IV	
Palonosetron	0.5 mg oral	
Ramosetron	0.3 mg IV	
Tropisetron	5 mg oral OR 5 mg IV	
Dexamethasone[b]	12 mg or 20 mg oral/IV	8 mg oral/IV daily or twice daily on days 2-4
Olanzapine	5 mg or 10 mg oral	5 mg or 10 mg oral on days 2-4
Moderate Risk (30%-90%): Aldesleukin, Alemtuzumab, Arsenic trioxide, Azacitidine, Bendamustine, Busulfan, Carboplatin, Clofarabine, Cyclophosphamide <1,500 mg/m^2, Cytarabine >1,000 mg/m^2, Daunorubicin, Daunorubicin and cytarabine liposomal, Doxorubicin, Epirubicin, Fam-trastuzumab deruxtecan-nxki, Idarubicin, Ifosfamide, Irinotecan, Irinetecan liposomal injection, Oxaliplatin, Romidepsin, Temozolomide, Thiotepa, Trabectidin		
5-HT$_3$ Antagonist		
Granisetron	2 mg oral or 1 mg IV or 10 mcg/kg IV or 1 patch or 10 mg SQ	
Ondansetron	8 mg oral twice daily or 8 mg IV or 0.15 mg/kg IV	
Palonosetron	0.5 mg oral or 0.25 mg IV	
Ramosetron	0.3 mg IV	
Tropisetron	5 mg oral or 5 mg IV	
Dexamethasone	8 mg oral/IV	8 mg oral/IV on days 2-3[c]
Low Risk (10%-30%): Aflibercept, Axicabtogene ciloleucel, Belinostat, Blinatumomab, Bortezomib, Brentuximab, Cabazitaxel, Carfilzomib, Cetuximab, Copanlisib, Cytarabine <1,000 mg/m^2, Decitabine, Docetaxel, Elotuzumab, Enfortumab vedotin-ejfv, Eribulin, Etoposide, Fluorouracil, Gemcitabine, Gemcitabine ozogamicin, Inotuzumab ozogamicin, Ixabepilone, Methotrexate, Mitomycin, Mitoxantrone, Moxetumomab pasudotox, Nab-paclitaxel, Necitumumab, Nelarabine, Paclitaxel (conventional and albumin-bound), Panitumumab, Pegylated liposomal doxorubicin, Prmetrexed, Pertuzumab, Tagraxofusp-erzs, Topotecan, Trastuzumab emtansine, Vinflunine		
Choose One:		

5-HT$_3$ Antagonist		
Granisetron	2 mg oral or 1 mg IV or 10 mcg/kg IV or 1 patch or 10 mg SQ	
Ondansetron	8 mg oral or IV	
Palonosetron	0.5 mg oral or 0.25 mg IV	
Ramosetron	0.3 mg IV	
Tropisetron	5 mg oral or IV	
OR		
Dexamethasone	8 mg oral or IV	
Minimal Risk (<10%): Avelumab, Atezolizumab, Bevacizumab, Bleomycin, Cemiplimab, 2-Chlorodeoxyadenosine, Cladribine, Daratumumab, Durvalumab, Emapalumab, Fludarabine, Ipilimumab, Nivolumab, Obinutuzumab, Ofatumumab, Pembrolizumab, Pralatrexate, Ramucirumab, Rituximab (IV and SQ), Trastuzumab, Vinblastine, Vincristine (conventional and liposomal), Vinorelbine		
No routine prophylactic antiemetics are needed		

[a] No additional 5-HT$_3$-RA is needed if netupitant/palonosetron is used.

[b] Dexamethasone dose on day 1 should be reduced to 12 mg when given with aprepitant, fosaprepitant, and netupitant/palonosetron due to drug interactions. Dexamethasone dose on days 2-4 should be omitted when used as antiemetic with anthracycline/cyclophosphamide combination regimen or carboplatin AUC ≥4.

[c] Only if regimen is known to cause delayed nausea/vomiting (eg, cyclophosphamide, doxorubicin, oxaliplatin).

Data from Reference [2].

PATHOPHYSIOLOGY

The three consecutive phases of emesis include nausea, retching, and vomiting. Nausea, the subjective feeling of the need to vomit, may be considered a separate and singular symptom. Retching is the labored movement of abdominal and thoracic muscles before vomiting. The final phase of emesis is vomiting, the forceful expulsion of gastric contents caused by GI retroperistalsis. The act of vomiting is coordinated by the brainstem, but requires the contractions of the abdominal muscles, pylorus, and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilation.[1] Vomiting should not be confused with regurgitation, an act in which the gastric or esophageal contents rise to the pharynx but is not usually associated with forceful ejection seen with vomiting. Accompanying autonomic symptoms of pallor, tachycardia, and diaphoresis account for many of the distressing feelings associated with emesis.

Vomiting is triggered by afferent impulses to the vomiting center (VC), a nucleus of cells in the medulla. Impulses are received from sensory centers, which include the chemoreceptor trigger zone (CTZ), cerebral cortex, and visceral afferents from the pharynx and GI tract. The VC integrates the afferent impulses, resulting in efferent impulses to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles, leading to vomiting.

The CTZ, located in the area postrema of the fourth ventricle of the brain, is a major chemosensory organ for emesis and is usually associated with chemically induced vomiting. Because of its location, blood-borne and cerebrospinal fluid toxins have easy access to the CTZ. Antineoplastic agents primarily stimulate this area rather than the cerebral cortex and visceral afferents. Pregnancy-associated vomiting probably occurs through stimulation of the CTZ.

Numerous neurotransmitter receptors are located in the VC, CTZ, and GI tract, including cholinergic, histaminic, dopaminergic, opiate, serotonergic, neurokinin (NK), and benzodiazepine receptors. Antineoplastic agents, their metabolites, or other emetic compounds theoretically trigger the process of emesis through stimulation of one or more of these receptors. Antiemetics have been developed to antagonize or block these emetogenic receptors.[3] See Fig. 53-1.

CLINICAL PRESENTATION

Nausea and vomiting is commonly seen in many clinical situations. Patients may present in varying degrees of distress summarized in the Patient Care Process (PCP). See Table 53-3 for clinical presentation of nausea and vomiting.

TABLE 53-3

Clinical Presentation of Nausea and Vomiting

General

Depending on severity of symptoms, patients may present in mild to severe distress

Symptoms

Simple: Self-limiting, resolves spontaneously, and requires only symptomatic therapy

Complex: Not relieved after administration of antiemetics; progressive deterioration of patient secondary to fluid-electrolyte imbalances; usually associated with noxious agents or psychogenic events

Signs

Simple: Patient complaint of queasiness or discomfort

Complex: Weight loss; fever; abdominal pain

Laboratory tests

Simple: None

Complex: Serum electrolyte concentrations; upper/lower GI evaluation

Other information

Fluid input and output

Medication history

Recent history of behavioral or visual changes, headache, pain, or stress

Family history positive for psychogenic vomiting

TREATMENT

Desired Outcomes

③The overall goal of antiemetic therapy is to prevent or eliminate nausea and vomiting. This should be accomplished without adverse effects or with clinically acceptable adverse effects. In addition to these clinical goals, appropriate cost issues should be considered, particularly in the management of chemotherapy-induced nausea and vomiting (CINV) and postoperative nausea and vomiting (PONV).

General Approach to Treatment

③Treatment options include drug and nondrug modalities such as relaxation, biofeedback, and hypnosis. Initially patients may choose to not treat or to self-medicate with nonprescription drugs. As symptoms become worse or are associated with more serious medical problems, patients are more likely to utilize prescription antiemetic drugs. When prescribed and used appropriately, these agents can provide relief; however, some patients will never be totally free of symptoms. This lack of relief is most disabling when it is associated with an unresolved medical problem or when the necessary therapy for this condition is the cause of the nausea or vomiting, as in the case of patients who are receiving antineoplastic agents of moderate or high emetic risk.

Nonpharmacologic Management

④Nonpharmacologic management of nausea and vomiting involves dietary, physical, or psychological strategies that are consistent with the etiology of nausea and vomiting. For patients who are suffering due to excessive or disagreeable food or beverage consumption, avoidance or moderation in dietary intake may lead to symptom resolution. Patients suffering from symptoms of systemic illness may quickly improve as their underlying condition resolves. Patients in whom these symptoms result from labyrinthine changes produced by motion may benefit quickly by assuming a stable physical position.

Nonpharmacologic interventions include relaxation, biofeedback, hypnosis, cognitive distraction, optimism, guided imagery, acupuncture, yoga, transcutaneous electrical stimulation, chewing gum, and systematic desensitization.[4–8] Chewing gum after certain surgical procedures improves bowel function and decreases time to first flatus as well as decreases the incidence of postoperative ileus.[6,7] Some of these modalities, such as acupuncture, are effective at preventing nausea and vomiting in the surgical population.[8] Other therapies, such as ginger and pyridoxine, may be beneficial in specific situations as with pregnancy associated nausea and vomiting.

Changes in diet such as restricting oral intake, eating smaller meals, avoiding spicy or fried foods, and instead eating bland foods such as with the BRAT diet (**B**ananas, **R**ice, **A**pplesauce, and **T**oast) can help alleviate symptoms.

Pharmacologic Therapy

Although many approaches to the treatment of nausea and vomiting have been suggested, antiemetic drugs (nonprescription and prescription) are most often recommended. These agents work in various ways and may be used singularly or in conjunction with each other, and have a number of delivery methods.

Factors that enable the clinician to choose the appropriate regimen include: (a) the suspected etiology of the symptoms; (b) the frequency, duration, and severity of the episodes; (c) the ability of the patient to use oral, rectal, injectable, or transdermal medications; and (d) the success of previous antiemetic medications. See Table 53-4 for dosing information of commonly available antiemetic preparations.

TABLE 53-4

Common Antiemetic Preparations and Adult Dosage Regimens[a]

Drug	Adult Dosage Regimen	Dosage Form/Route	Availability
Antacids: Useful with simple nausea/vomiting *Adverse drug reactions: Magnesium products—diarrhea; Aluminum or calcium products—constipation*			
Antacids (various)	15-30 mL every 2-4 hr prn	Liquid/oral	Nonprescription
Antihistaminic–Anticholinergic Agents: Especially problematic in the elderly; increased risk of complications in patients with benign prostatic hyperplasia (BPH), narrow angle glaucoma, or asthma *Adverse drug reactions: Drowsiness, confusion, blurred vision, dry mouth, urinary retention*			
Dimenhydrinate (Dramamine)	50-100 mg every 4-6 hr prn	Tab, chew tab, cap	Nonprescription
Diphenhydramine (Benadryl)	25-50 mg every 4-6 hr prn 10-50 mg every 2-4 hr prn	Tab, cap, liquid IM, IV	Prescription/Nonprescription
Hydroxyzine (Vistaril, Atarax)	25-100 mg every 4-6 hr prn	Tab, (unlabeled use)	Prescription
Meclizine (Bonine, Antivert)	12.5-25 mg 1 hr before travel; repeat every 12-24 hr prn	Tab, chew tab	Prescription/Nonprescription
Scopolamine (Transderm Scop)	1.5 mg every 72 hr	Transdermal patch	Prescription
Trimethobenzamide (Tigan)	300 mg three to four times daily 200 mg three to four times daily	Cap IM	Prescription

Benzodiazepine: Used for ANV but is contraindicated with olanzapine *Adverse drug reactions: Dizziness, sedation, appetite changes, memory impairment; observe for additive sedation especially if used with narcotic analgesics*			
Lorazepam (Ativan)	0.5-2 mg on night before and morning of chemotherapy	Tab, IV	Prescription (C-IV)
Butyrophenones: Used for breakthrough CINV; Droperidol has limited use *Adverse drug reactions: Haloperidol—sedation, constipation, hypotension, extrapyramidal symptoms (EPS); Droperidol—QTc prolongation and/or torsade de pointes, 12-lead electrocardiogram prior to administration, followed by cardiac monitoring for 2-3 hr after administration*			
Haloperidol (Haldol)	0.5-2 mg every 4-6 hr prn	Tab, liquid, IM, IV	Prescription
Droperidol (Inapsine)[b]	2.5 mg; additional 1.25 mg may be given	IM, IV	Prescription
Cannabinoids: Used for breakthrough CINV *Adverse drug reactions: Eurphoria, somnolence, xerostomia*			
Dronabinol (Marinol, Syndros)	5-15 mg/m^2 every 2-4 hr prn 4.2-12.6 mg/m^2 every 2-4 hr prn	Cap Oral solution	Prescription (C-III)
Nabilone (Cesamet)	1-2 mg twice daily	Cap	Prescription (C-II)
Corticosteroids: Useful as a single agent or combination therapy for prophylaxis of CINV or PONV *Adverse drug reactions: Insomnia, GI symptoms, agitation, appetite stimulation, hypertension, and hyperglycemia*			
Dexamethasone	See Table 53-7 for CINV dosing and Table 53-6 for PONV dosing	Tab, IV	Prescription
Histamine (H2) Antagonists: Useful with nausea secondary to heartburn or GERD *Adverse drug reactions: Headache, constipation, or diarrhea*			
Cimetidine (Tagamet HB)	200 mg twice daily prn	Tab	Nonprescription
Famotidine (Pepcid AC)	10 mg twice daily prn	Tab	Nonprescription
Nizatidine (Axid AR)	75 mg twice daily prn	Tab	Nonprescription
5-Hydroxytryptamine-3 Receptor Antagonists: Useful as a single-agent or combination therapy for prophylaxis of CINV or PONV *Adverse drug reactions: Asthenia, constipation, headache*			
	See Table 53-7 for CINV dosing and Table 53-6 for PONV dosing	Tab, IV	Prescription
Miscellaneous Agents • **Metoclopramide:** Prokinetic activity useful in diabetic gastroparesis. *Adverse drug reactions: Asthenia, headache, somnolence, EPS* • *Amisulpride: Mainly used in PONV; avoid use in severe renal impairment. Adverse drug reactions: Increased serum prolactin, prolonged QTc interval* • **Olanzapine**: Use with caution in elderly; contraindicated with benzodiazepines. *Adverse drug reactions: Sedation, prolonged QTc interval, EPS* • **Pyridoxine:** Used in NVP. May be used alone or in combination with doxylamine 12.5 mg. Combination product available as prescription. *Adverse drug reactions: Drowsiness, headache*			

Metoclopramide (Reglan)	10-20 mg (0.5-2 mg/kg) four times daily	Tab, IV	Prescription
Olanzapine (Zyprexa)	5-10 mg daily	Tab	Prescription
Pyridoxine (Vitamin B_6)	10-25 mg orally three to four times daily	Tab, cap	Nonprescription
Amisulpride	5-10 mg once either before or after surgery	5-10 mg once either before or after surgery	Prescription
Phenothiazines: Useful in simple nausea/vomiting or breakthrough CINV *Adverse drug reactions: Prolonged QTc interval, constipation, dizziness, tachycardia, tardive dyskinesia, drowsiness*			
Chlorpromazine (Thorazine)	10-25 mg every 4-6 hr prn	Tab, liquid	Prescription
	25-50 mg every 4-6 hr prn	IM, IV	
Prochlorperazine (Compazine)	5-10 mg every 4-6 hr prn	Tab, liquid	Prescription
	5-10 mg every 3-4 hr prn	IM	
	2.5-10 mg every 3-4 hr prn	IV	Prescription
	25 mg twice daily prn	Supp	Prescription
Promethazine (Phenergan)	12.5-25 mg every 4-6 hr prn	Tab, liquid, IM, IV, supp	Prescription
Substance P/Neurokinin-1 Receptor Antagonist: Useful in combination therapy for prophylaxis of CINV and PONV *Adverse drug reactions: Constipation, diarrhea, headache, hiccups, dyspepsia, and fatigue*			
Aprepitant	See Table 53-7 for CINV dosing and Table 53-6 for PONV dosing	Cap, IV	Prescription
Fosaprepitant		IV	Prescription
Fosnetupitant-palonosetron		IV	Prescription
Netupitant/palonosetron		Cap	Prescription
Rolapitant		Cap	Prescription

[a] All regimens should be monitored for resolution or occurrence of nausea and vomiting as well as maintaining an adequate hydration status.

[b] See text for warnings.

ANV, anticipatory nausea and vomiting; C-II, C-III, and C-IV, controlled substance schedule 2, 3, and 4, respectively; cap, capsule; chew tab, chewable tablet; CINV, chemotherapy-induced nausea and vomiting; GI, gastrointestinal; GERD, gastroesophageal reflux disease; liquid, oral syrup, concentrate, or suspension; NVP, nausea and vomiting of pregnancy; PONV, postoperative nausea and vomiting; supp, rectal suppository; tab, tablet.

The treatment of simple nausea and vomiting often involves self-care from a list of nonprescription products. Both nonprescription and prescription drugs are useful in the treatment of simple nausea and vomiting in small, infrequently administered doses and are associated with minimal side effects. As the symptoms persist or become worse, prescription medications may be chosen, either as single-agent therapy or in combination.

The management of complex nausea and vomiting, such as in patients who are receiving antineoplastic agents, may require initial combination therapy. In combination regimens, the goal is to achieve symptomatic control through administration of agents with different pharmacologic mechanisms of action.

Antacids

Patients who are experiencing simple nausea and vomiting may initially use antacids, as many of these products are readily available without a prescription. Single or combination products, especially those containing magnesium hydroxide, aluminum hydroxide, and/or calcium carbonate, may provide rapid relief, primarily through gastric acid neutralization. These agents are most effective for those with symptoms related to acid reflux or heartburn and must be used with caution in those who experience acute or chronic kidney disease due to the risk of accumulation. These agents may exacerbate other GI complaints that accompany nausea and vomiting, such as diarrhea or constipation, so attention must be paid to which of these agents may worsen these other conditions.

Antihistamine–Anticholinergic Drugs

Antiemetic drugs from the antihistaminic–anticholinergic category work on muscarinic and histamine receptors in the VC and the vestibular system that stimulate nausea and vomiting. These agents are frequently initiated as self-care to prevent nausea and vomiting associated with motion disturbances such as vertigo and motion sickness.

Benzodiazepines

Benzodiazepines are relatively weak antiemetics and are primarily used for their anxiolytic activity to prevent anxiety or anticipatory nausea and vomiting (ANV) that may occur in patients experiencing suboptimal CINV control. Lorazepam may be used as an adjunct to other antiemetics in patients experiencing ANV.

Butyrophenones

Haloperidol and droperidol work by blocking dopaminergic stimulation of the CTZ, which in turn decreases the incidence of nausea and vomiting. The use of these agents may be complicated by their propensity to cause extrapyramidal symptoms and QTc prolongation. For these reasons, haloperidol is not considered first-line therapy for uncomplicated nausea and vomiting but has been used in breakthrough CINV and palliative care situations.[9] Droperidol use is limited to rescue antiemetic for PONV. The current labeling of droperidol recommends that all patients should undergo a 12-lead electrocardiogram prior to administration, followed by cardiac monitoring for 2 to 3 hours after administration because of the possibility of the development of potentially fatal QT prolongation and/or torsade de pointes.[10]

Cannabinoids

Cannabinoids have complex effects on the CNS and their effects at cannabinoid receptor 1 (CB1) in neural tissues may explain efficacy in CINV. Medicinal cannabis can be in the use of cannabis or cannabinoids in order to treat various conditions, including nausea and vomiting. Cannabinoids can be administered in a variety of methods including orally, topically, or sublingually. Oral dronabinol and nabilone, FDA-approved synthetic analogs of delta-9-tetrahydrocannabinol (THC), may be therapeutic options when CINV is refractory to other antiemetics. Medicinal marijuana has been approved for use in over half of states in the United States; however, its use remains debatable.[11] There is limited data to support the use of smoked or ingested cannabis for CINV. FDA-approved cannabinoids and medicinal cannabis improved symptoms in comparison to placebo or active comparators in some trials.[12] The combination of dronabinol and prochlorperazine was significantly more effective when used in combination for the treatment of CINV versus either agent alone.[11] Cannabinoids have the advantage of being effective for other cancer-related side effects such as pain or use as an appetite stimulant.[11–13] Despite these advantages, cannabinoids are not indicated as first-line agents. There is also concern that chronic cannabis use can lead to cyclic nausea and vomiting, which is called cannabinoid hyperemesis syndrome. This syndrome is primarily treated by supportive care, frequent hot showers, and cannabis cessation.[14]

Corticosteroids

Corticosteroids have demonstrated antiemetic efficacy since the initial recognition that patients who received prednisone as part of their Hodgkin's disease protocol appeared to develop less nausea and vomiting than did those patients who were treated with protocols that excluded this agent. The site and mechanism of action of corticosteroids for CINV and PONV are unknown.

Dexamethasone is the most commonly studied and used corticosteroid in the management of CINV and PONV, either as a single agent or in combination with 5-hydroxytryptamine-3 receptor antagonists (5-HT_3-RAs). Dexamethasone is effective in the prevention of both CINV acute emesis and delayed nausea and vomiting when used alone or in combination.[15,16] Given the risk of corticosteroids such as hyperglycemia, fluid retention, and even psychosis, steroids are not indicated for the treatment of simple nausea and vomiting.

H2-Receptor Antagonists

Histamine-2 receptor antagonists (H2RA) work by decreasing gastric acid production and are used to manage simple nausea and vomiting associated with heartburn or gastroesophageal reflux. Except for potential drug interactions with a variety of oral chemotherapy agents, these agents cause few side effects when used for episodic relief.

5-Hydroxytryptamine-3 Receptor Antagonists

5-Hydroxytryptamine-3 receptor antagonists (5-HT_3-RAs) block serotonin receptors on sensory vagal fibers in the gut wall; thus, blocking the acute phase of CINV. These agents do not completely block the acute phase of CINV and are less efficacious in preventing the delayed phase, but they are considered the standard of care in the management of CINV, PONV, and radiation-induced nausea and vomiting (RINV).[2,16]

The 5-HT_3-RAs are considered equivalent when used in equipotent doses/schedules so any agent may be used for CINV. Intravenous doses of ondansetron should not exceed 16 mg due to QTc prolongation.[17] Palonosetron has less effect on QTc and a significantly longer half-life compared to other 5-HT_3-RAs. Granisetron is available in two nonoral formulations: a transdermal patch and an extended-release subcutaneous injection. The granisetron patch should be applied 24 to 48 hours prior to chemotherapy and may be worn for up to 7 days. The choice of 5-HT_3-RAs for CINV should be based on route of administration, potential side effects, and cost concerns.

Metoclopramide

Metoclopramide works by blocking dopaminergic receptors centrally in the CTZ. It also increases lower esophageal sphincter tone, aids gastric emptying, and accelerates transit through the small bowel, possibly through the release of acetylcholine. The prokinetic activity of metoclopramide makes it useful in patients with nausea and vomiting associated with diabetic gastroparesis. Due to the risk of extrapyramidal symptoms, metoclopramide should be used with caution if used in combination with other dopamine antagonists such as olanzapine or haloperidol.

Neurokinin-1 Receptor Antagonists

Substance P is a peptide neurotransmitter in the NK family whose preferred receptor is the NK_1 receptor. The acute phase of CINV is thought to be mediated by both serotonin and substance P, where substance P is believed to be the primary mediator of the delayed phase. An NK_1 receptor antagonist in combination with other antiemetics is now standard of care for prevention of CINV in both adults and children receiving highly emetogenic chemotherapy.[2] Aprepitant, fosaprepitant, and rolapitant are NK_1 receptor antagonists currently in clinical use, along with two combination NK_1 receptor antagonist/5-HT_3-RA co-formulated products, netupitant/palonosetron (NEPA) and fosnetupitant-palonosetron.[18]

Aprepitant has the potential for numerous drug interactions because it is a substrate and moderate inhibitor of cytochrome isoenzyme CYP3A4 as well as a weak inducer of CYP2C9. It can increase serum concentrations of many drugs, including chemotherapeutic agents metabolized by CYP3A4 such as anthracyclines, bosutinib, cabazitaxel, cyclophosphamide, and ifosfamide.[19] Other significant drug interactions include decreased effectiveness of estrogen-containing contraceptives (oral, patches, vaginal rings), and a decrease in the international normalized ratio when used with warfarin.[20] The dose of oral dexamethasone within the antiemetic regimen should be reduced 50% when coadministered with aprepitant, because of the 2.2-fold increase in observed area under the plasma-concentration-versus-time curve.[21] Conversely, if dexamethasone is used as part of the chemotherapy regimen, the dexamethasone dose should remain the same.

Fosaprepitant is an injectable form of aprepitant approved by the FDA as an IV substitute for oral aprepitant, given on day 1 only of the CINV prevention regimen.[22] Drug interactions are likely reduced with fosaprepitant compared to oral aprepitant.[19]

Rolapitant has a significantly longer half-life in comparison with aprepitant (7 days vs 9 hours) and therefore should only be administered once in a 2-week period.[23] Although rolapitant has no effects on CYP3A4, it does inhibit p-glycoprotein/ABCB1 and CYP2D6, which may lead to drug interactions with certain antineoplastic agents, including doxorubicin, liposomal vincristine, pazopanib, topotecan, and venetoclax. Postmarketing reports of anaphylaxis, anaphylactic shock, and severe hypersensitivity reactions during or shortly after initiation of IV rolapitant resulted in an FDA warning for this product. Patients with known hypersensitivity to components of IV rolapitant, including soybean oil, may be at an increased risk of reactions. All patients should be screened for cross-reactive allergens including soybeans and other legumes prior to administration.[23]

NEPA, when given in one dose combined with dexamethasone, was noninferior to a combination regimen of aprepitant, granisetron, and dexamethasone regimen in individuals receiving moderate or highly emetogenic chemotherapy.[24] Netupitant is also a moderate inhibitor of CYP3A4, and requires a significant decrease in the dexamethasone dose when used together. Drug interactions with other CYP3A4 substrates would also be expected with NEPA.[18]

Olanzapine

Olanzapine is an antipsychotic that blocks several neurotransmitters including dopamine, serotonin, adrenergic, histamine (H_1), and 5-HT_3-RA. Olanzapine in combination with aprepitant/fosaprepitant, 5-HT_3-RA, and dexamethasone significantly improved nausea control after highly emetogenic chemotherapy.[25] The American Society of Clinical Oncology (ASCO) antiemesis practice guidelines include olanzapine as part of the standard four drug combination antiemetic regimen for highly emetogenic chemotherapy.[2] Sedation is the most common side effects with olanzapine; it should be used with caution in older adults and dose reductions may be necessary in this population.[26,2727,28]

Phenothiazines

Phenothiazines have been the most widely prescribed antiemetic agents and appear to block dopamine receptors, most likely in the CTZ. They are marketed in an array of dosage forms, none of which appears to be more efficacious than the other. These agents may be most practical for long-term treatment and are inexpensive in comparison with newer drugs. Rectal administration is a reasonable alternative for patients in whom oral or parenteral administration is not feasible.

Phenothiazines are most useful in adult patients with simple nausea and vomiting. Intravenously administered prochlorperazine provided faster and more complete relief with less drowsiness than IV promethazine in adult patients treated in an emergency department for nausea and vomiting associated with uncomplicated gastritis or gastroenteritis.[28]

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

There are five categories of CINV: acute, delayed, anticipatory, breakthrough, and refractory. Nausea and vomiting that occurs within 24 hours of chemotherapy administration is defined as acute CINV, whereas when it starts more than 24 hours after chemotherapy administration, it is defined as delayed CINV.[29]

Nausea or vomiting that occurs prior to receiving chemotherapy is termed anticipatory nausea and vomiting (ANV). ANV is believed to be a learned, conditioned, or psychological response that occurs in about 14% of patients by the third cycle of chemotherapy.[4,31,32] ANV triggers include tastes, odors, sights, or thoughts associated with chemotherapy. Risk factors associated with ANV include experiencing CINV with prior chemotherapy cycles and anxiety before receiving chemotherapy.[4] In the setting of optimal antiemetic prophylaxis and no prior history of emesis, reported chemotherapy-induced ANV is rare. Use of newer antiemetic regimens appears to have resulted in a decreased rate of ANV.[30]

Breakthrough nausea and vomiting is defined as emesis occurring despite prophylactic administration of antiemetics and requiring the use of rescue antiemetics. Breakthrough emesis occurs in 10% to 40% of patients treated with antiemetics.[29]

Refractory nausea and vomiting is evident when there is a poor response to antiemetic regimens in prior cycles of chemotherapy. It is also important to rule out other potential causes of nausea and vomiting in the cancer population that are listed in Table 53-5.[2]

TABLE 53-5

Nonchemotherapy Etiologies of Nausea and Vomiting in Cancer Patients

- Malignancy (primary tumor or metastases)
- Brain
- Meninges
- Hepatic
- Gastrointestinal
- Uremia
- Infections (septicemia, local)
- Radiation therapy

Data from Reference [25].

⑤ The primary goal with CINV is to prevent nausea and/or vomiting, and the emetic risk of the chemotherapeutic regimen is a major factor to consider when selecting a prophylactic regimen.[2]

Clinical practice guidelines for the use of antiemetics in CINV have been published by the National Comprehensive Cancer Network (NCCN), the Multinational Association of Supportive Care in Cancer/European Society of Medical Oncology (MASCC/ESMO), and ASCO.[2,28,32] The NCCN guidelines are updated annually, while the ASCO and ESMO guidelines are updated less frequently. Despite the demonstrated improvement in outcomes with the use of these practice guidelines, they are underutilized by a high percentage of practitioners.[32] Product availability and recommended doses are often institution-specific and may vary considerably from the doses listed in Table 53-2.

Principles of Antiemetic Use for CINV

The ASCO, MASCC, and NCCN consensus groups share several of the principles listed below that are important for the effective prevention of CINV in adults.[2,27,312,28,32]

1. The primary goal of emesis prevention is no nausea and/or vomiting throughout the period of emetic risk.

2. The duration of emetic risk is 2 days for patients receiving moderately emetogenic chemotherapy and 3 days for highly emetogenic chemotherapy. Emetic prophylaxis should be provided through the entire period of risk.
3. The selection of the antiemetic regimen should be based on the chemotherapy drug with highest emetogenicity (see Table 53-2). Prior emetic experience and patient-specific factors should also be considered.
4. When given in equipotent doses, oral and IV 5-HT_3-RAs are equivalent in efficacy.
5. The toxicities of antiemetics should be considered and managed appropriately.

Prophylaxis of CINV

Each of the practice guidelines states that the most effective classes of drugs for the prevention of acute emesis, anticipatory, breakthrough, and refractory CINV are the 5-HT_3-RAs, NK_1 receptor antagonists, olanzapine, and glucocorticoids (especially dexamethasone). Treatment recommendations for the different categories of emesis are outlined in Table 53-2. For a full treatment algorithm, see Chapter 150, “Supportive Care.”

RADIATION-INDUCED NAUSEA AND VOMITING

Nausea and vomiting associated with radiation therapy (RT) is not well understood and often underestimated by radiation oncologists.[34] RINV is neither as predictable nor as severe as CINV, and many patients receiving RT will not experience nausea or vomiting. RINV occurs in approximately one-third of patients, is site dependent, and can have a substantial impact on a patient’s quality of life. Risk factors associated with the development of RINV include combination chemoradiotherapy, prior CINV, upper abdomen RT, and field size.[27] For more information on treatment options for the prevention of RINV, see Chapter 150, “Supportive Care.”

POSTOPERATIVE NAUSEA AND VOMITING

PONV in adults occurs in 30% of patients and usually within 24 hours of undergoing anesthesia.[35] Patients with multiple risk factors are at highest risk for PONV (Table 53-6). In adults with 0, 1, 2, 3, and 4 of the risk factors in Table 53-6, the incidence of PONV is 10%, 20%, 40%, 60%, and 80%, respectively. Those who are found to have 0 to one risk factors are considered low risk, those with two risk factors are considered medium risk, and those with three or more risk factors are considered high risk. In children, those with no risk factors are considered low risk, those with one to two risk factors are considered as medium risk, and those with three or more risk factors are considered high risk. The use of a risk assessment tool can help identify patients most likely to benefit from prophylaxis.[16,36,37]

TABLE 53-6

Risk Factors for Postoperative Nausea and Vomiting (PONV)

- **Patient-related factors**
- Age less than 50 years old
- Female sex (two to three times greater incidence of PONV vs male sex)
- Nonsmoker
- History of PONV or motion sickness (threefold increase in incidence of PONV)
- Hydration status

- **Factors related to anesthesia**
- Use of general anesthesia
- Use of volatile anesthetics
- Nitrous oxide use for > 1 hr
- Use of opioids (intraoperative or postoperative)

- **Factors related to surgery**
- Type of surgical procedure (laparoscopic, gynecological, cholecystectomy)
- Duration of surgery

Data from References [36,37].

In addition to using prophylactic antiemetics in moderate- and high-risk patients, other strategies to prevent PONV include using regional rather than systemic anesthesia, propofol, and hydration, as well as avoiding the use of extended duration nitrous oxide, volatile anesthetics, or opioids.[16]

Prophylaxis of PONV

⑥ Patients at highest risk of vomiting (>2 risk factors) should receive three or four prophylactic antiemetics from different pharmacologic classes, while those at moderate risk (1-2 risk factors) should receive a two-drug regimen. Adherence to consensus guidelines for prophylaxis and treatment of PONV decrease emetic episodes.[16] Timing the administration of the antiemetic is vital to the efficacy with PONV and may vary dependent upon the agent. Scopolamine patches must be initiated the evening before the surgery or at least 2 hours prior, whereas NK_1 antagonists should be given during the induction of anesthesia; all other agents are recommended to be administered at the end of the surgery. Pharmacological options for the prevention of PONV include $5\text{-}HT_3$-RAs, an NK_1 antagonist, corticosteroids, droperidol, haloperidol, amisulpride, antihistamines, and anticholinergics.

Ondansetron is considered the “gold standard” 5-HT3-RA and has the most data supporting its use at the end of surgical procedures. It has greater antivomiting activity versus antinausea activity and is as effective as dexamethasone and IV haloperidol. However, it is less effective than longer acting agents such as aprepitant, ramosetron, granisetron, and fosaprepitant in decreasing emesis beyond 24 hours, and less effective than palonosetron for decreasing the incidence of PONV.[16,38–4142–45]Ondansetron has greater efficacy compared to metoclopramide.[16]

Steroids, such as dexamethasone and methylprednisolone, are useful low-cost agents for preventing PONV. The recommended dose of dexamethasone ranges from 4 to 10 mg; however, there is limited evidence to support the use of doses greater than 8 mg. Dexamethasone should be administered after the induction of anesthesia, and when given in a single dose, has low risk of postoperative infections and only a mild increase in blood glucose values.[16,34,46] Palonosetron is more efficacious than dexamethasone in reducing PONV over a 24-hour interval.[47] One unique advantage dexamethasone has over other agents is that it decreases the need for other analgesic agents.[48] In patients undergoing hip and knee arthroplasty, methylprednisolone in doses from 40 mg to 125 mg decreased both PONV and pain.[4916,50,51]

When evaluating antiemetics for PONV, there are several options including agents with antidopaminergic, antihistaminic, or anticholinergic activity. Intravenous amisulpride at 5 mg was more effective when compared to placebo in decreasing nausea severity. While it may lead to small increases in prolactin levels at lower doses, it was not found to be associated with QTc prolongation or a high risk of extrapyramidal symptoms, but may lead to small increases in prolactin levels.[53] Droperidol can be effective for PONV when administered at the end of surgery; however, its use has been limited due to the risk of sudden cardiac death.[16] Haloperidol, while not an FDA-approved agent for PONV, was efficacious and safe at low doses (0.5-2 mg) for prevention of PONV when compared to 5-HT3 antagonist.[42] Diphenhydramine at a dose of 50 mg decreased the incidence of PONV following outpatient laparoscopic gynecologic surgery.[43]

Several other agents have been studied to decrease the incidence of PONV including gabapentin and midazolam. When used 1 to 2 hours before laparoscopic cholecystectomy gabapentin decreased both pain and the incidence of PONV.[54] When administered at induction of anesthesia midazolam reduced the incidence of PONV, and when combined with other antiemetics has increased efficacy.[55]

Guidelines advocate the for use of a combination of antiemetics; however, the optimal regimen when using more than two agents is more ambiguous.[16] The choice should be based on use of different mechanisms of action, adverse effect profiles, and cost. When evaluating two-drug regimens, the combination of a 5-HT3-RA plus dexamethasone 4 to 8 mg is considered the cornerstone of therapy.[44] There is also strong evidence to support the use of aprepitant plus dexamethasone. The addition of low-dose midazolam has increased efficacy, and amisulpride plus either ondansetron or dexamethasone was beneficial when compared to either ondansetron or dexamethasone alone.[16,45] Table 53-7 summarizes the doses for prophylactic antiemetics from the consensus guidelines.[16]

In children, those with no risk factors who are considered low risk can either use no antiemetic or either a 5-HT3- RA or dexamethasone. In those with one to two risk factors and are at a medium risk for PONV, it is recommended to use a combination of a 5-HT$_3$-RA plus dexamethasone. For those with three or more risk factors and at a high risk for developing PONV, the recommendation is to use a 5-HT$_3$-RA plus dexamethasone, or consider total intravenous anesthesia.[16]

TABLE 53-7

Recommended Prophylactic Doses of Selected Antiemetics for Postoperative Nausea and Vomiting in Adults and Postoperative Vomiting in Children

Drug	Adult Dose	Pediatric Dose (IV)	Timing of Dose[a]
Amisulpride	5 mg	Not included in consensus guidelines	At induction
Aprepitant	40 mg orally	3 mg/kg up to 125 mg	At induction
Dexamethasone	4-8 mg IV	150 mcg/kg up to 5 mg	At induction
Dimenhydrinate	1 mg/kg IV	0.5 mg/kg up to 25 mg	Not specified
Droperidol[b]	0.625 mg IV	10-15 mcg/kg up to 1.25 mg	At end of surgery
Granisetron	0.35-3 mg IV	40 mcg/kg up to 0.6 mg	At end of surgery
Haloperidol	0.5-2 mg (IM or IV)	Not included in consensus guidelines	Not specified
Methylprednisolone	40 mg IV	Not included in consensus guidelines	Not specified
Metoclopramide	10 mg	Not included in consensus guidelines	Not specified
Ondansetron	4 mg IV, 8 mg orally or orally disintegrating tablet	50-100 mcg/kg up to 4 mg	At end of surgery
Palonosetron	0.075 mg IV	0.5-1.5 mcg/kg	At induction
Promethazine[b]	6.25 mg IV	Not included in consensus guidelines	At induction
Ramosetron	0.3 mg IV	Not included in consensus guidelines	At end of surgery
Rolapitant	70-200 mg orally	Not included in consensus guidelines	At induction
Scopolamine	Transdermal patch	Not included in consensus guidelines	Prior evening or 24 hr before surgery
Tropisetron	2 mg IV	0.1 mg/kg up to 2 mg	At end of surgery

[a] Based on recommendations from consensus guidelines.

Data from Reference [16].

Treatment of PONV

Patients who experience PONV after receiving prophylactic treatment with a combination of a 5-HT_3-RA plus dexamethasone should be given rescue therapy from a different drug class such as a phenothiazine, metoclopramide, or droperidol. Repeating the agent given for PONV prophylaxis within 6 hours of surgery offers no additional benefit. A repeated dose of a 5-HT_3-RA is not effective in treatment of PONV.[58,59] If an emetic episode occurs more than 6 hours postoperatively, a second dose of a 5-HT$_3$-RA can be used; however, it is not recommended to repeat doses of either dexamethasone or transdermal scopolamine.[16]

If no prophylaxis was given initially, the recommended treatment is low-dose 5-HT$_3$-RA such as ondansetron 4 mg orally or IV or ramosetron 0.3 mg IV. Alternative treatments for established PONV include haloperidol 1 mg, vestipitant 4 to 36 mg, amisulpride 5 to 10 mg, droperidol 0.625 mg IV, and promethazine 6.25 mg IV.[50–52]

DISORDERS OF BALANCE

Disorders of balance include vertigo, dizziness, and motion sickness. The etiology of these complaints may include diseases that are infectious, postinfectious, demyelinative, vascular, neoplastic, degenerative, traumatic, toxic, psychogenic, or idiopathic. Symptoms of imbalance perceived by the patient present a particular clinical challenge.

⑦ Beneficial therapy for patients with balance disorders can most reliably be found among the antihistaminic–anticholinergic agents. However, the precise mechanisms of action of these agents are unknown. Oral regimens of antihistaminic–anticholinergic agents given one to several times each day may be effective, especially when the first dose is administered prior to motion.

Motion sickness may be associated with nausea and vomiting; however medication is more effective when given prophylactically. Scopolamine is effective for the prevention of motion sickness and is considered first line for this indication.[56] The usefulness of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system (patch) that increased patient satisfaction and decreased untoward side effects. The patch should be placed several hours before the anticipated motion exposure. First-generation sedating antihistamines are also effective. However, second-generation nonsedating antihistamines, ondansetron, and ginger root are not effective in the prevention and treatment of motion sickness.[56]

ANTIEMETIC USE DURING PREGNANCY

As many as 80% of pregnant females experience nausea and 50% will have vomiting or retching.[56] The severity of the symptoms varies considerably, from mild nausea to incapacitating nausea and vomiting. The etiology of nausea and vomiting of pregnancy (NVP) is not well understood, but theories proposed include hormonal stimulus, evolutionary adaptation, and psychological predisposition.[56,57] Symptoms are self-limited for a majority of females, although up to 3% develop hyperemesis gravidarum, a serious condition marked by severe physical symptoms and/or medical complications requiring hospitalization.[58] Hyperemesis gravidarum may result in volume contraction, starvation, and electrolyte abnormalities.

Treatment recommendations for the management of NVP are available from the American College of Obstetricians and Gynecologists (ACOG).[59,60] Prevention of NVP should be the initial treatment approach. A prenatal vitamin should be started 1 month prior to becoming pregnant, which may help reduce the incidence and severity of NVP.[60] Dietary changes and/or lifestyle modifications such as eating smaller, more frequent meals every 1 to 2 hours, and avoiding foods or odors that trigger symptoms are recommended. Ginger is beneficial in reducing nausea but not vomiting.[59] Persistent nausea and/or vomiting leads to the consideration of drug therapy at a time when teratogenic potential of each agent must be considered. Pyridoxine (vitamin B$_6$), with or without doxylamine, is recommended as first-line therapy.[59] A delayed-release formulation of doxylamine and pyridoxine hydrochloride (Diclegis®) is available as a prescription product.[59] Dimenhydrinate, diphenhydramine, prochlorperazine, or promethazine may also be considered in the treatment of NVP.

Patients with persistent NVP or who show signs of dehydration should receive intravenous hydration with thiamine administered before dextrose to prevent Wernicke encephalopathy. Enteral tube feedings should be considered in females with hyperemesis gravidarum not responsive to medical therapy and who cannot maintain weight.[59] Ondansetron, promethazine, and metoclopramide have similar effectiveness for hyperemesis gravidarum, although ondansetron may be better tolerated due to less adverse effects.[61–64] Glucocorticoids, like methylprednisolone, may be used in patients with severe NVP or hyperemesis gravidarum, but should only be used after 10 weeks of gestation due to the increased risk of cleft lip.[56]

ANTIEMETIC USE IN SPECIAL POPULATIONS

Gastroenteritis in Children

Nausea and vomiting associated with pediatric gastroenteritis is usually self-limited and improves with correction of dehydration. The majority of patients can be successfully treated with oral rehydration therapy. Pediatric practitioners may prescribe antiemetics for intractable vomiting due to gastroenteritis. The use of promethazine is contraindicated in patients less than 2 years old and should be used with caution in older children due to the potential risk of fatal respiratory depression.[65] Administration of ondansetron is associated with decreased vomiting, a reduced need for intravenous rehydration therapy, and preventing hospital admissions.[66,67,69,70]

Antiemetic Use in Older Patients

Many of the commonly used antiemetics are on the Beers Criteria list, which are medications that may be inappropriate in older adults due to the risks outweighing the benefits.[68] These include first-generation antihistamines and scopolamine due to their highly anticholinergic side effects. Metoclopramide is also on the Beers list because it may cause extrapyramidal effects including tardive dyskinesia especially in frail older adults.[69] Ondansetron may be considered a preferred antiemetic in older adults; however, consider drug-drug interactions and potential adverse effects before prescribing.[70]

EVALUATION OF EMETIC OUTCOMES

In assessing emetic outcomes, standardized monitoring criteria should include a subjective assessment and objective parameters. For patients on chemotherapy, evaluation of emetic outcomes should occur after the administration of each chemotherapy cycle. In regards to PONV, the patient should be monitored both immediately post procedure as well as for delayed symptoms.

SELF-ASSESSMENT QUESTIONS

1. Which of the following medications would be considered first line in the prevention of nausea and vomiting related to motion sickness?

A. Scopolamine

B. Ondansetron

C. Cetirizine

D. Ginger

2. Which of the following treatments is contraindicated in children less than 2 years old due to the risk of fatal respiratory depression?

A. Metoclopramide

B. Promethazine

C. Probiotics

D. Ondansetron

3. GJ is an 82-year-old White male who just had a knee replacement and is experiencing postoperative nausea and vomiting (PONV). The provider would like to use a safe medication in this older patient. Which of the following is the best recommendation for GJ?

A. Promethazine

B. Metoclopramide

C. Scopolamine

D. Ondansetron

4. An appropriate nonpharmacologic recommendation for a pregnant patient with nausea and vomiting includes:

A. Eating large meals

B. Eating two times a day

C. Using ginger

D. Smelling trigger odors

5. MJ is a 32-year-old Black female who is pregnant with her first child and nonpharmacologic therapies are no longer helping her nausea and vomiting. Which of the following is the recommended first-line therapy for the treatment of nausea and vomiting in a pregnant woman?

A. Meclizine

B. Metoclopramide

C. Ondansetron

D. Doxylamine

6. A 35-year-old female patient is found to be at high risk for developing PONV. Which of the following would be the BEST therapy for prevention of PONV in this patient?

A. Haloperidol + Droperidol

B. Ondansetron + Dexamethasone + Midazolam

C. Dexamethasone + Droperidol +Haloperidol

D. Rolapitant + Promethazine

7. Which of the following 5-HT_3-RA has the longest duration of action?

A. Granisetron

B. Ramosetron

C. Ondansetron

D. Palonosetron

8. A patient undergoing chemotherapy is having a difficult time taking their oral ondansetron during chemotherapy treatments, and has no IV access. Which of the following 5-HT_3-RA class could be used in this patient?

A. Tropisetron

B. Granisetron

C. Palonosetron

D. Fosaprepitant

9. Which of the following is considered a risk factor for developing postoperative nausea and vomiting?

A. Use of local anesthetics

B. Positive smoking history

C. History of motion sickness

D. Age >70 years old

10. When should dexamethasone be administered when used for prevention of postoperative nausea and vomiting in relationship to the operative procedure?

A. The night prior to the procedure

B. 1 hour prior to the procedure

C. At the end of the procedure

D. After the induction of anesthesia

11. What antiemetic can be used to treat nausea and vomiting, but when used chronically it can cause hyperemesis syndrome?

A. Lorazepam

B. Ondansetron

C. Promethazine

D. Cannabinoids

12. Which agent is considered the first-line treatment for pregnancy-associated nausea and vomiting?

A. Pyridoxine + doxylamine

B. Droperidol

C. Scopolamine

D. Olanzapine + dexamethasone

13. The _______ diet can help decrease the symptoms of nausea and vomiting.

A. DASH

B. BRAT

C. Keto

D. Raw food

14. Which NK-1 antagonist requires dosing on multiple days post-chemotherapy?

A. Aprepitant

B. Netupitan-palonosetron

C. Rolapitant

D. Fosaprepitant

15. What laboratory abnormalities may be found secondary to nausea and vomiting?

A. Elevated WBCs

B. Low platelets

C. Low sodium

D. Elevated CRP

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Scopolamine is effective for the prevention of motion sickness and is considered first line for this indication. The usefulness of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system (patch) that increased patient satisfaction and decreased untoward side effects. The patch should be placed several hours before the anticipated motion exposure.

2. **B.** The use of promethazine is contraindicated in patients less than 2 years old and should be used with caution in older children due to the potential risk of fatal respiratory depression.

3. **D.** Ondansetron may be considered a preferred antiemetic in older adults; however, consider drug–drug interactions and potential adverse effects before prescribing.

4. **C.** Dietary changes and/or lifestyle modifications such as eating smaller, more frequent meals every 1 to 2 hours, and avoiding foods or odors that trigger symptoms are recommended. Ginger is beneficial in reducing nausea but not vomiting.

5. **D.** Persistent nausea and/or vomiting leads to the consideration of drug therapy at a time when teratogenic potential of each agent must be considered. Pyridoxine (vitamin B6), with or without doxylamine, is recommended as first-line therapy. The US Food and Drug Administration (FDA) approved a delayed-release formulation of doxylamine and pyridoxine hydrochloride (Diclegis[R]) as a prescription product.

6. **B.** Patients at highest risk of vomiting (> 2 risk factors) should receive two three or morefour prophylactic antiemetics from different pharmacologic classes. Of the available 5-HT3-RAs, ondansetron is still considered the “gold standard” agent and has the most data supporting its use at the end of surgical procedures. When evaluating 2 drug regimens, the combination of a 5-HT3- RAs plus dexamethasone 4-8 mg is considered the cornerstone of therapy. Considering other regimens, the addition of low dose midazolam has shown to have increase efficacy.

7. **D.** Palonosetron has a significantly longer half-life compared to other 5-HT3-RAs. The half lives are as follows: Granisetron (9 hours); Ramosetron (5.8 hours); Ondansetron (6 hours); Palonosetron (40 hours).

8. **B.** Granisetron is the only option that is also available as a transdermal patch.

9. **C.** The answer is a history of motion sickness. General or volatile anesthetics put patients at a higher risk of PONV. Patients who do not smoke are

actually at a higher risk of PONV than those who do, and patients less than 50 years old are at a higher risk. This leaves a history of PONV or motion sickness that increases the risk for PONV.

10. **D.** Dexamethasone should be administered after the induction of anesthesia.

11. **D.** There is also concern that chronic cannabis use can lead to cyclic nausea and vomiting, which is called cannabinoid hyperemesis syndrome. This syndrome is primarily treated by supportive care, frequent hot showers, and cannabis cessation.

12. **A.** Glucocorticoids, like methylprednisolone, may be used in patients with severe NVP or hyperemesis gravidarum, but should be used only after 10 weeks of gestation due to the increased risk of cleft lip.

13. **B.** Changes in diet such as restricting oral intake, eating smaller meals, avoiding spicy or fried foods, and instead eating bland foods such as with the BRAT diet (Bananas, Rice, Applesauce, and Toast) can help alleviate symptoms.

14. **A.** Aprepitant requires dosing on days 1-3 surrounding chemotherapy.

15. **C.** Various electrolyte derrangements may occur as a result of vomiting, including hyponatremia, or low sodium levels.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 54: Diarrhea, Constipation, and Irritable Bowel Syndrome

Patricia H. Fabel; Kayce Shealy

KEY CONCEPTS

KEY CONCEPTS

① Diarrhea is caused by many viral and bacterial organisms. It is most often a minor discomfort, not life-threatening, and usually self-limited.

② The four pathophysiologic mechanisms of diarrhea have been linked to the four broad diarrheal groups, which are secretory, osmotic, exudative, and altered intestinal transit. The three mechanisms by which absorption occurs from the intestines are active transport, diffusion, and solvent drag.

③ Management of diarrhea focuses on preventing excessive water and electrolyte losses, dietary care, relieving symptoms, treating curable causes, and treating secondary disorders.

④ Bismuth subsalicylate is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea, but may cause interactions with several components if given excessively.

⑤ Constipation is defined as difficult or infrequent passage of stool, at times associated with straining or a feeling of incomplete defecation.

⑥ Underlying causes of constipation should be identified when possible and corrective measures taken (eg, alteration of diet or treatment of diseases such as hypothyroidism).

⑦ The foundation of treatment of constipation is dietary fiber or bulk-forming laxatives that provide 20 to 25 g/day of raw fiber.

⑧ Irritable bowel syndrome (IBS) is one of the most common GI disorders characterized by lower abdominal pain, disturbed defecation, and bloating. Many non-GI manifestations also exist with IBS. Visceral hypersensitivity is a major culprit in the pathophysiology of the disease.

⑨ Diarrhea-predominant IBS should be managed by dietary modification and drugs such as rifaximin or eluxadoline when diet changes alone are insufficient to promote control of symptoms.

⑩ Several drug classes are involved in the treatment of the pain associated with IBS including tricyclic compounds and the gut-selective calcium channel blockers.

BEYOND THE BOOK

Go to www.loperamidesafety.org/resources and review the fact sheets for healthcare providers aimed at helping identify potential loperamide misuse. Reflecting on your role on the healthcare team, what can you do to ensure safe and appropriate loperamide use?

DIARRHEA

Diarrhea is a troublesome discomfort that affects most individuals in the United States at some point in their lives and can be thought of as both a symptom and a sign. Usually diarrheal episodes begin abruptly and subside within 1 or 2 days without treatment. This chapter focuses primarily on noninfectious diarrhea, with only minor reference to infectious diarrhea (see Chapter 136 for a discussion of gastrointestinal infections). Diarrhea is often a symptom of a systemic disease, and not all possible causes of diarrhea are discussed in this chapter. Acute diarrhea is commonly defined as less than 14-day duration, persistent diarrhea as more than 14-day duration, and chronic diarrhea as more than 30-day duration.

To understand diarrhea, one must have a reasonable definition of the condition; unfortunately, the literature is extremely variable on this. Simply put, diarrhea is an increased frequency and decreased consistency of fecal discharge as compared with an individual's normal bowel pattern. Frequency and consistency are variable within and between individuals. For example, some individuals defecate as often as three times per day, whereas others defecate only two or three times per week. A Western diet usually produces a daily stool weighing between 100 and 300 g, depending on the amount of nonabsorbable materials (mainly carbohydrates) consumed. Patients with serious diarrhea may have a daily stool weight in excess of 300 g; however, a subset of patients experience frequent small, watery passages. Additionally, vegetable fiber-rich diets, such as those consumed in some Eastern cultures (eg, those in Africa), produce stools weighing more than 300 g/day.

Diarrhea may be associated with a specific disease of the intestines or secondary to a disease outside the intestines. For instance, bacillary dysentery directly affects the gut, whereas diabetes mellitus causes neuropathic diarrheal episodes. Furthermore, diarrhea can be considered as acute or chronic disease. Infectious diarrhea is often acute; diarrhea secondary to diabetes is chronic. Congenital disorders in GI ion transport mechanisms are another cause of chronic diarrhea.[1] Whether acute or chronic, diarrhea has the same pathophysiologic causes that help in identification of specific treatments.

Epidemiology

The epidemiology of diarrhea varies in developed versus developing countries.[2] In the United States, diarrheal illnesses are usually not reported to the Centers for Disease Control and Prevention (CDC) unless associated with an outbreak or an unusual organism or condition. For example, the acquired immune deficiency syndrome (AIDS) has been identified with protracted diarrheal illness. Diarrhea is a major problem in daycare centers and nursing homes, probably because early childhood and senescence plus environmental conditions are risk factors. Although an exact epidemiologic profile in the United States is not available through the CDC or published literature, 25% of individuals in the United States experience an episode of acute diarrhea annually with increased incidence in children and older adults.[3] In developing countries, diarrhea is a leading cause of illness and death in children, creating a tremendous economic strain on healthcare costs.

① Most cases of acute diarrhea are self-limiting infections caused by food or waterborne organisms, such as viruses, bacteria, or protozoa.[4] Although viruses are more commonly associated with acute gastroenteritis, bacteria are responsible for more cases of acute diarrhea. Evaluation of a noninfectious cause is considered if diarrhea persists and no infectious organism can be identified, or if the patient falls into a high-risk category for metabolic complications with persistent diarrhea. Common causative bacterial organisms include *Shigella*, *Salmonella*, *Campylobacter*, *Staphylococcus*, and *Escherichia coli*. Foodborne bacterial infection is a major concern, as several major food poisoning episodes have occurred that were traced to poor sanitary conditions in meat processing plants. Acute viral infections are attributed mostly to the Norwalk and rotavirus groups.

Physiology

In the fasting state, 9 L of fluid enters the proximal small intestine each day. Of this fluid, 2 L is ingested through diet, while the remainder consists of internal secretions. Because of meal content, duodenal chyme is usually hypertonic. When chyme reaches the ileum, the osmolality adjusts to that of plasma, with most dietary fat, carbohydrate, and protein being absorbed. The volume of ileal chyme decreases to about 1 L/day on entering the colon, which is further reduced by colonic absorption to 100 mL daily. If the small intestine water absorption capacity is exceeded, chyme overloads the colon, resulting in diarrhea. In humans, the colon absorptive capacity is about 5 L daily. Colonic fluid transport is critical to water and electrolyte balance.

Absorption of fluid from the intestines back into the blood occurs by three mechanisms: active transport, diffusion, and solvent drag. Active transport and diffusion are the mechanisms of sodium transport. Because of the high luminal sodium concentration (142 mEq/L [mmol/L]), sodium diffuses from the sodium-rich gut into epithelial cells, where it is actively pumped into the blood and exchanged with chloride to maintain an isoelectric condition across the epithelial membrane. Hydrogen ions are transported by an indirect mechanism in the upper small intestine. As sodium is absorbed, hydrogen ions are secreted into the gut. Hydrogen ions then combine with bicarbonate ions to form carbonic acid, which then dissociates into carbon dioxide and water. Carbon dioxide readily diffuses into the blood for expiration through the lung. The water remains in the chyme.

Paracellular pathways are major routes of ion movement. As ions, monosaccharides, and amino acids are actively transported, an osmotic pressure is created, drawing water and electrolytes across the intestinal wall. This pathway accounts for significant amounts of ion transport, especially sodium. Sodium plays an important role in stimulating glucose absorption. Glucose and amino acids are actively transported into the blood via a sodium-dependent cotransport mechanism. Cotransport absorption mechanisms of glucose–sodium and amino acid–sodium are extremely important for treating diarrhea.

Gut motility influences absorption and secretion. The amount of time in which luminal content is in contact with the epithelium is under neural and hormonal control. Neurohormonal substances, such as angiotensin, vasopressin, glucocorticoid, aldosterone, and neurotransmitters, also regulate ion transport.

Pathophysiology

② Four general pathophysiologic mechanisms disrupt water and electrolyte balance, leading to diarrhea, and are the basis of diagnosis and therapy. These are (a) a change in active ion transport by either decreased sodium absorption or increased chloride secretion; (b) change in intestinal motility; (c) increase in luminal osmolarity; and (d) increase in tissue hydrostatic pressure. These mechanisms have been related to four broad clinical diarrheal groups: secretory, osmotic, exudative, and altered intestinal transit.

Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. Substances that cause excess secretion include vasoactive intestinal peptide (VIP) from a pancreatic tumor, unabsorbed dietary fat in steatorrhea, laxatives, hormones (such as secretion), bacterial toxins, and excessive bile salts. Many of these agents stimulate intracellular cyclic adenosine monophosphate and inhibit Na^+/K^+-adenosine triphosphatase (ATPase), leading to increased secretion. Also, many of these mediators inhibit ion absorption simultaneously. Secretory diarrhea is recognized by large stool volumes (more than 1 L/day) with normal ionic contents and osmolality approximately equal to plasma. Fasting does not alter the stool volume in these patients.

Poorly absorbed substances retain intestinal fluids, resulting in osmotic diarrhea. This process occurs with malabsorption syndromes, lactose intolerance, administration of divalent ions (eg, magnesium-containing antacids), or consumption of poorly soluble carbohydrate (eg, lactulose). As a poorly soluble solute is transported, the gut adjusts the osmolality to that of plasma; in so doing, water and electrolytes flux into the lumen. Clinically, osmotic diarrhea is distinguishable from other types, as it ceases if the patient resorts to a fasting state.

Inflammatory diseases of the GI tract discharge mucus, serum proteins, and blood into the gut. Sometimes bowel movements consist only of mucus, exudate, and blood. Exudative diarrhea affects other absorptive, secretory, or motility functions to account for the large stool volume associated with this disorder.

Altered intestinal motility produces diarrhea by three mechanisms: (1) reduction of contact time in the small intestine, (2) premature emptying of the colon, and (3) bacterial overgrowth. Chyme must be exposed to intestinal epithelium for a sufficient time period to enable normal absorption and secretion processes to occur. If this contact time decreases, diarrhea results. Intestinal resection or bypass surgery and drugs (such as metoclopramide) cause this type of diarrhea. On the other hand, an increased time of exposure allows fecal bacteria overgrowth. A characteristic small intestine diarrheal pattern is rapid, small, coupling bursts of waves. These waves are inefficient, do not allow absorption, and rapidly dump chyme into the colon. Once in the colon, chyme exceeds the colonic capability to absorb water.

Examination of the Stool

Stool characteristics are important in assessing the etiology of diarrhea. A description of the frequency, volume, consistency, and color provides diagnostic clues. For instance, diarrhea starting in the small intestine produces a copious, watery or fatty (greasy), and foul-smelling stool; contains undigested food particles; and is usually free from gross blood. Colonic diarrhea appears as small, pasty, and sometimes bloody or mucoid movements. Rectal tenesmus with flatus accompanies large intestinal diarrhea.

Clinical Presentation

Table 54-1 outlines the clinical presentation of diarrhea, and Table 54-2 shows common drug-induced causes of diarrhea. A medication history is extremely important in identifying drug-induced diarrhea. Many agents, including antibiotics and other drugs, cause diarrhea or, less commonly, pseudomembranous colitis. Self-inflicted laxative abuse for weight loss is common.

TABLE 54-1

Clinical Presentation of Diarrhea

General • Usually, acute diarrheal episodes subside within 72 hours of onset, whereas chronic diarrhea involves frequent attacks over extended time periods.
Signs and symptoms • Abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise. • Bowel movements are frequent and never bloody, and diarrhea lasts 12–60 hours. • Intermittent periumbilical or lower right quadrant pain with cramps and audible bowel sounds is characteristic of small intestinal disease. • When pain is present in large intestinal diarrhea, it is a gripping, aching sensation with tenesmus (straining, ineffective, and painful stooling). Pain localizes to the hypogastric region, right or left lower quadrant, or sacral region. • In chronic diarrhea, a history of previous bouts, weight loss, anorexia, and chronic weakness are important findings.
Physical examination • Typically demonstrates hyperperistalsis with borborygmi and generalized or local tenderness.
Laboratory tests • Stool analysis studies include examination for microorganisms, blood, mucus, fat, osmolality, pH, electrolyte and mineral concentration, and cultures. • Stool test kits are useful for detecting GI viruses, particularly rotavirus. • Antibody serologic testing shows rising titers over a 3- to 6-day period, but this test is not practical and is nonspecific. • Occasionally, total daily stool volume is also determined. • Direct endoscopic visualization and biopsy of the colon may be undertaken to assess for the presence of conditions such as colitis or cancer. • Radiographic studies are helpful in neoplastic and inflammatory conditions.

TABLE 54-2

Drugs Causing Diarrhea

Laxatives
    Antacids containing magnesium

Antineoplastics
Auranofin (gold salt)
Antibiotics
    Clindamycin
    Tetracyclines
    Sulfonamides
    Any broad-spectrum antibiotic

Antihypertensives
    Reserpine
    Guanethidine
    Methyldopa
    Guanabenz
    Guanadrel
    Angiotensin-converting enzyme inhibitors

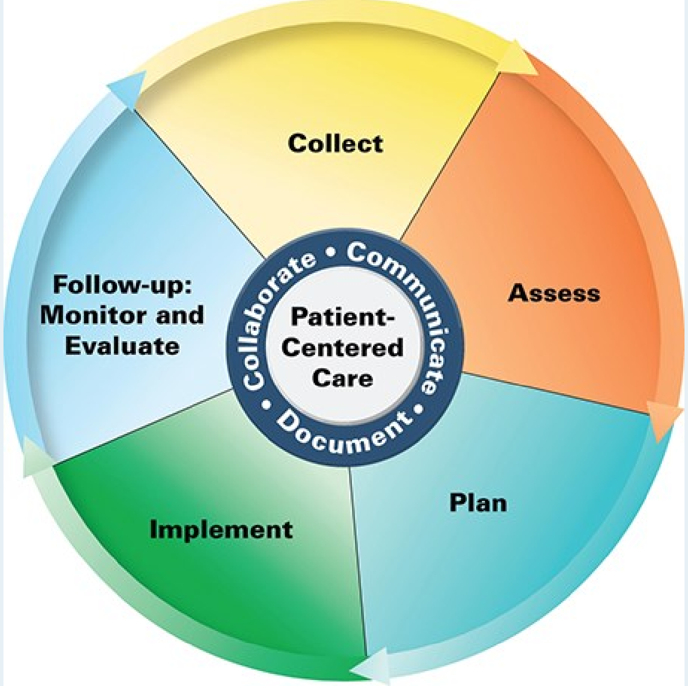
Cholinergics
    Bethanechol
    Neostigmine

Cardiac agents
    Quinidine
    Digitalis
    Digoxin

Nonsteroidal anti-inflammatory drugs
Misoprostol
Colchicine
Proton pump inhibitors
H_2-receptor blockers

Most acute diarrhea is self-limiting, subsiding within 72 hours. However, infants, young children, older patients, and debilitated persons are at risk for morbid and mortal events in prolonged or voluminous diarrhea. These groups are at risk for water, electrolyte, and acid-base disturbances, and potentially cardiovascular collapse and death. The prognosis for chronic diarrhea depends on the cause; for example, diarrhea secondary to diabetes mellitus waxes and wanes throughout life.

Patient Care Process for Diarrhea



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics
- Patient medical, family, social history, and dietary habits
- Current medications, including nonprescription
- Vital signs and weight
- Laboratory tests depending upon medical history and other presenting symptoms
  - Thyroid function tests, complete blood count, glucose, serum electrolytes

Assess

- Underlying causes of diarrhea (see Tables 54-1 and 54-2)
- Severity and duration of symptoms
- Patient preference for symptom resolution
- Ability/willingness to pay for treatment options

Plan*

- Treat specific cause of diarrhea (ie, diabetes, infectious)
- Increase fluid intake using oral rehydration solutions (ORS) (Table 54-3)
- Antidiarrheal medication (Table 54-4)
- Monitor symptom resolution for efficacy, and pronounced constipation for safety
- Patient education regarding importance of prevention dehydration

- Referral to other providers when appropriate

Implement

- Educate the patient on all aspects of the treatment plan
- Schedule follow-up to monitor safety and efficacy of treatment plan

Follow-up: Monitor and Evaluate

- Determine resolution of diarrhea and related symptoms
- Evaluate for signs and symptoms of dehydration
- Assess for presence of adverse effects (eg, abdominal pain, constipation)
- Assess patient adherence to treatment plan
- Reevaluate periodically until resolution

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

Treatment and Prevention

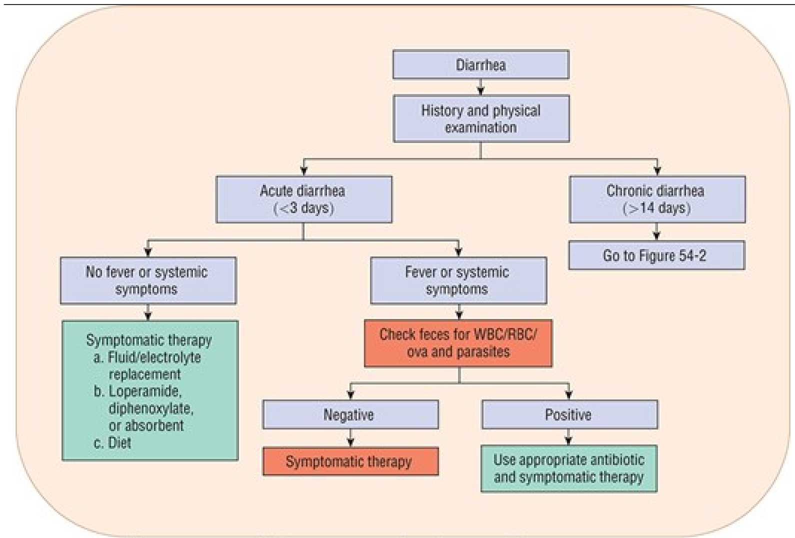
Acute viral diarrheal illness often occurs in daycare centers and nursing homes. Because person-to-person contact is the mechanism by which viral disease spreads, isolation techniques must be initiated. For bacterial, parasitic, and protozoal infections, strict food handling, sanitation, water, and other environmental hygiene practices can prevent transmission. If diarrhea is secondary to another illness, controlling the primary condition is necessary. Antibiotics and bismuth subsalicylate are advocated to prevent traveler's diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables.[5,6]

Desired Outcome

③ If prevention is unsuccessful and diarrhea occurs, therapeutic goals are to (a) manage the diet; (b) prevent excessive water, electrolyte, and acid-base disturbances; (c) provide symptomatic relief; (d) treat curable causes; and (e) manage secondary disorders causing diarrhea (Figs. 54-1 and 54-2).

FIGURE 54-1

Recommendations for treating acute diarrhea. Follow the following steps: (a) Perform a complete history and physical examination. (b) Is the diarrhea acute or chronic? If chronic diarrhea, go to Fig. 54-2. (c) If acute diarrhea, check for fever and/or systemic signs and symptoms (ie, toxic patient). If systemic illness (fever, anorexia, or volume depletion), check for an infectious source. If positive for infectious diarrhea, use appropriate antibiotic/anthelmintic drug and symptomatic therapy. If negative for infectious cause, use only symptomatic treatment. (d) If no systemic findings, then use symptomatic therapy based on severity of volume depletion, oral or parenteral fluid/electrolytes, antidiarrheal agents (see Table 54-4), and diet (RBC, red blood cells; WBC, white blood cells).



Diarrhea
History and physical examination
Acute diarrhea (<3 days)
Chronic diarrhea (>14 days)
Go to Figure 54-2
No fever or systemic symptoms
Fever or systemic symptoms
Symptomatic therapy
a. Fluid/electrolyte replacement
b. Loperamide, diphenoxylate, or absorbent
c. Diet
Check feces for WBC/RBC/ ova and parasites
Negative
Positive
Symptomatic therapy
Use appropriate antibiotic and symptomatic therapy

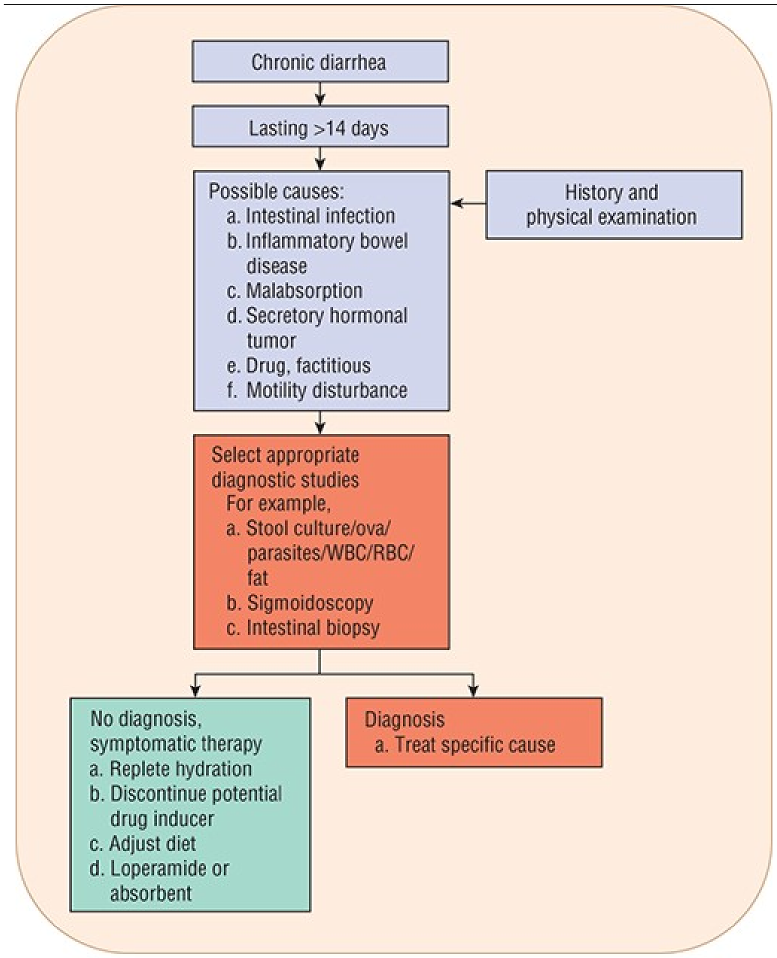
FIGURE 54-2

Recommendations for treating chronic diarrhea. Follow the following steps: (a) Perform a careful history and physical examination. (b) The possible causes of chronic diarrhea are many. These can be classified into intestinal infections (bacterial or protozoal), inflammatory disease (Crohn's disease or ulcerative colitis), malabsorption (lactose intolerance), secretory hormonal tumor (intestinal carcinoid tumor or vasoactive intestinal peptide-secreting tumor [VIPoma]), drug (antacid), factitious (laxative abuse), or motility disturbance (diabetes mellitus, irritable bowel syndrome, or hyperthyroidism). (c) If the diagnosis is uncertain, selected appropriate diagnostic studies should be ordered. (d) Once diagnosed, treatment is planned for the underlying cause with symptomatic antidiarrheal therapy. (e) If no specific cause can be identified, symptomatic therapy is prescribed (RBC, red blood cells; WBC, white blood cells).



Chronic diarrhea
Lasting >14 days
Possible causes:
a. Intestinal infection
b. Inflammatory bowel disease
c. Malabsorption
d. Secretory hormonal tumor
e. Drug, factitious
f. Motility disturbance
History and physical examination
Select appropriate diagnostic studies
For example,
a. Stool culture/ova/parasites/WBC/RBC/fat
b. Sigmoidoscopy
c. Intestinal biopsy
No diagnosis, symptomatic therapy
a. Replete hydration
b. Discontinue potential drug inducer
c. Adjust diet
d. Loperamide or absorbent
Diagnosis
a. Treat specific cause

Clinicians must clearly understand that diarrhea, like a cough, may be a body defense mechanism for ridding itself of harmful substances or pathogens. The correct therapeutic response is not necessarily to stop diarrhea at all costs.

Nonpharmacologic Management

Dietary management is a first priority in the treatment of diarrhea. Feeding should continue in children with acute bacterial diarrhea. Fed children have less morbidity and mortality, whether or not they receive oral rehydration fluids. Studies are not available in older patients or in other high-risk groups to determine the value of continued feeding in bacterial diarrhea.

Water and Electrolytes

Rehydration and maintenance of water and electrolytes are primary treatment goals until the diarrheal episode ends. If the patient is volume depleted, rehydration should be directed at replacing water and electrolytes to normal body composition. Then water and electrolyte composition are maintained by replacing losses. Many patients will not develop volume depletion and therefore will only require maintenance fluid and electrolyte therapy. Parenteral and enteral routes may be used for supplying water and electrolytes. If vomiting and dehydration are not severe, the enteral route is the less costly and preferred. In the United States, many commercial oral rehydration preparations are available (Table 54-3).

TABLE 54-3

Oral Rehydration Solutions

	WHO-ORS[a]	Pedialyte[b] (Ross)	CeraLyte (Cera Products)	Enfalyte (Mead Johnson)
Osmolality (mOsm/kg or mmol/kg)	245	250	220	167

Bicarbonate	30	—	—	—
Calcium	—	—	—	—
Magnesium	—	—	—	—
Sulfate	—	—	—	—
Phosphate	—	—	—	—

[a] The World Health Organization (WHO) reduced osmolarity oral rehydration solution.

[b] Carbohydrate is glucose.

[c] Rice syrup solids are carbohydrate source.

Because of concerns about hypernatremia, physicians continue to hospitalize patients and use IV fluids to correct fluid and electrolyte deficits in severe dehydration. Oral solutions are strongly recommended when tolerated to limit side effects, reduce costs, and improve recovery.[7] In developing countries, the WHO oral rehydration solution (WHO-ORS) saves the lives of millions of children annually.

During diarrhea, the small intestine retains its ability to actively transport monosaccharides such as glucose. Glucose actively carries sodium with water and other electrolytes. The WHO recommends an ORS with a lower osmolarity, sodium content, and glucose load (see Table 54-3).[8] A separate oral supplement of zinc 20 mg daily for 10 days in addition to ORS significantly reduces the severity and duration of acute diarrhea in developing countries.[2] ORS is a lifesaving treatment for millions afflicted in developing countries. Acceptance in developed countries is less enthusiastic; however, the advantage of this product in reducing hospitalizations may prove its use as a cost-effective alternative, saving millions of dollars in healthcare expenditures.

Pharmacologic Therapy

Various drugs have been used to treat diarrheal attacks (Table 54-4), including antimotility agents, adsorbents, antisecretory compounds, antibiotics, enzymes, and intestinal microflora. Usually these drugs are not curative but palliative.

TABLE 54-4

Selected Antidiarrheal Preparations

	Dose Form	Adult Dose
Antimotility		
Diphenoxylate	2.5 mg/tablet 2.5 mg/5 mL	5 mg four times daily; do not exceed 20 mg/day
Loperamide	2 mg/capsule	Initially 4 mg, and then 2 mg after each loose stool; do not exceed 16 mg/day
Paregoric	2 mg/5 mL (morphine)	5-10 mL one to four times daily
Opium tincture	10 mg/mL (morphine)	0.6 mL four times daily
Difenoxin	1 mg/tablet	Two tablets, and then one tablet after each loose stool; up to eight tablets per day
Adsorbents		
Kaolin-pectin mixture	5.7 g kaolin + 130.2 mg pectin/30 mL	30-120 mL after each loose stool
Polycarbophil	500 mg/tablet	Chew 2 tablets four times daily or after each loose stool; do not exceed 12 tablets per day
Attapulgite	750 mg/15 mL 300 mg/7.5 mL 750 mg/tablet 600 mg/tablet 300 mg/tablet	1,200-1,500 mg after each loose bowel movement or every 2 hours; up to 9,000 mg/day
Antisecretory		
Bismuth subsalicylate	1,050 mg/30 mL 262 mg/15 mL 524 mg/15 mL 262 mg/tablet	Two tablets or 30 mL every 30 minutes to 1 hour as needed up to eight doses per day
Enzymes (lactase)		
	1,250 neutral lactase units/4 drops	Three to four drops taken with milk or dairy product
	3,300 FCC lactase units per tablet	

Bacterial replacement (*Lactobacillus acidophilus*, *Lactobacillus bulgaricus*)		Two tablets or one granule packet three to four times daily; give with milk, juice, or water
Octreotide	0.05 mg/mL 0.1 mg/mL 0.5 mg/mL	Initial: 50 mcg subcutaneously One to two times per day and titrate dose based on indication up to 600 mcg/day in two to four divided doses

Opiates and Their Derivatives

Opiates and opioid derivatives (a) delay the transit of intraluminal contents or (b) increase gut capacity, prolonging contact and absorption. Enkephalins, which are endogenous opioid substances, regulate fluid movement across the mucosa by stimulating absorptive processes. Limitations to the use of opiates include an addiction potential (a real concern with long-term use) and potential for worsening of diarrhea in selected infectious diarrhea.

Most opiates act through peripheral and central mechanisms with the exception of loperamide, which acts only peripherally. Loperamide is antisecretory; it inhibits the calcium-binding protein calmodulin, controlling chloride secretion. Loperamide, available as 2 mg capsules or 1 mg/5 mL solution (both are nonprescription products), is suggested for managing acute and chronic diarrhea. The usual adult dose for acute diarrhea is initially 4 mg orally, followed by 2 mg after each loose stool, up to 16 mg/day. Used correctly, this agent has rare side effects, such as dizziness and constipation. If the diarrhea is concurrent with a high fever or bloody stool, the patient should be referred to a physician. Also, diarrhea lasting 48 hours beyond initiating loperamide warrants medical attention. Loperamide can also be used in traveler's diarrhea. It is comparable to bismuth subsalicylate for treatment of this disorder.[5] The Food and Drug Administration (FDA) has released a warning about using high doses of loperamide for euphoria as it can lead to serious side effects including cardiovascular problems.[9] The packaging of loperamide has been reduced to minimize abuse.[10]

Diphenoxylate is available as a 2.5-mg tablet and as a 2.5 mg/5 mL solution. A small amount of atropine (0.025 mg) is included in the product to discourage abuse. In adults, when taken as 2.5 to 5 mg three or four times daily, not to exceed a 20 mg total daily dose, diphenoxylate is rarely toxic. Some patients may complain of atropinism (blurred vision, dry mouth, and urinary hesitancy). Like loperamide, it should not be used in patients who are at risk of bacterial enteritis with *E. coli*, *Shigella*, or *Salmonella*.

Difenoxin, a diphenoxylate derivative also chemically related to meperidine, is also combined with atropine and has the same uses, precautions, and side effects. Marketed as a 1-mg tablet, the adult dosage is 2 mg initially, followed by 1 mg after each loose stool, not to exceed 8 mg/day.

Paregoric, camphorated tincture of opium, is marketed as a 2 mg/5 mL solution and is indicated for managing both acute and chronic diarrhea. It is not widely prescribed today because of its abuse potential.

Adsorbents

Adsorbents are used for symptomatic relief. These products, many not requiring a prescription, are nontoxic, but their effectiveness remains unproven. Adsorbents are nonspecific in their action; they adsorb nutrients, toxins, drugs, and digestive juices. Polycarbophil absorbs 60 times its weight in water and can be used to treat both diarrhea and constipation. It is a nonprescription product and is sold as a 500-mg chewable tablet. This hydrophilic, nonabsorbable product is safe and may be taken four times daily, up to 6 g/day in adults. See Table 54-4 for selected antidiarrheal preparations.

Antisecretory Agents

Bismuth subsalicylate have antisecretory, anti-inflammatory, and antibacterial effects. As a nonprescription product, it is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea. Bismuth subsalicylate dosage strengths are a 262-mg chewable tablet, 262-mg/5 mL liquid, and 524-mg/15 mL liquid. The usual adult dose is two tablets or 30 mL every 30 minutes to 1 hour up to eight doses per day.

④ Bismuth subsalicylate contains multiple components that might be toxic if given in excess to prevent or treat diarrhea. For instance, an active ingredient is salicylate, which may interact with anticoagulants or may produce salicylism (tinnitus, nausea, and vomiting). Bismuth reduces tetracycline absorption and may interfere with select GI radiographic studies. Patients may complain of a darkening of the tongue and stools with repeat administration. Salicylate can induce gout attacks in susceptible individuals.

Bismuth subsalicylate suspension is useful in the treatment of secretory diarrhea of infectious etiology as well. With a dose of 30 mL every 30 minutes for eight doses, unformed stools decrease in the first 24 hours. Bismuth subsalicylate may also be effective in preventing traveler's diarrhea.

Octreotide, a synthetic octapeptide analog of endogenous somatostatin, is effective for the symptomatic treatment of carcinoid tumors and other peptide-secreting tumors, dumping syndrome, and chemotherapy-induced diarrhea.[11] It has had limited success in patients with AIDS-associated diarrhea and short-bowel syndrome, does not appear to have an advantage over various opiate derivatives in the treatment of chronic idiopathic diarrhea, and has the disadvantage of being administered by injection.[4] Metastatic intestinal carcinoid tumors secrete excessive amounts of vasoactive substances, including histamine, bradykinin, serotonin (5-hydroxytryptamine, 5-HT), and prostaglandins. Primary carcinoid tumors occur throughout the GI tract, with most in the ileum. Predominant signs and symptoms experienced by patients with these tumors are attributable to excessive concentrations of 5-hydroxytryptophan and 5-HT. The totality of their clinical effects is termed the carcinoid syndrome. Some patients have a violent, watery diarrhea with abdominal cramping. Initially, diarrhea might be managed with various agents such as codeine, diphenoxylate, cyproheptadine, methysergide, phenoxybenzamine, or methyldopa, but octreotide is now considered first-line therapy for carcinoid syndrome.

Octreotide blocks the release of 5-HT and many other active peptides and has been effective in controlling diarrhea and flushing. It is reported to have direct inhibitory effects on intestinal secretion and stimulatory effects on intestinal absorption. Non–gastrin-secreting adenomas of the pancreas are tumors associated with profuse watery diarrhea. This condition has been referred to as Verner–Morrison syndrome, watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome, pancreatic cholera, watery diarrhea syndrome, and vasoactive intestinal peptide-secreting tumor (VIPoma). Excessive secretion of VIP from a retroperitoneal or pancreatic tumor produces most of the clinical features. Surgical tumor dissection is the treatment of choice. In nonsurgical candidates, the profuse watery diarrhea and other symptoms commonly encountered are managed with octreotide.

The dose of octreotide varies with the indication, disease severity, and patient response.[11] For managing diarrhea and flushing associated with carcinoid tumors in adults, the initial dosage range is 100 to 600 mcg/day in two to four divided doses subcutaneously for 2 weeks. For controlling secretory diarrhea of VIPomas, the dosage range is 200 to 300 mcg/day in two to four divided doses for 2 weeks. Some patients may require higher doses for symptomatic control. Patients responding to these initial doses may be switched to Sandostatin LAR Depot, a long-acting octreotide formulation. Initial doses consist of 20 mg given intramuscularly intragluteally at 4-week intervals for 2 months. During the first 2 weeks of therapy the short-acting formulation should be administered subcutaneously. At the end of 2 months, patients with good symptom control may have the dose reduced to 10 mg every 4 weeks, while those without sufficient symptom control may have the dose increased to 30 mg every 4 weeks. For patients experiencing recurrence of symptoms on the 10 mg dose, dosage adjustment to 20 mg should be made. Patients with carcinoid tumors or VIPomas may experience periodic exacerbation of symptoms. Subcutaneous octreotide for several days should be reinstituted in these individuals. In so-called carcinoid crisis, octreotide is given as an IV infusion at 50 mcg/hr for 8 to 24 hours.

Because octreotide inhibits many other GI hormones, it has a variety of intestinal side effects. With prolonged use, gallbladder and biliary tract complications such as cholelithiasis may occur. Approximately 5% to 10% of patients complain of nausea, diarrhea, and abdominal pain. Local injection pain occurs with about an 8% incidence. With high doses, octreotide may reduce dietary fat absorption, leading to steatorrhea.

Two other somatostatin analogs, lanreotide and vapreotide, have been studied.[4] Lanreotide is approved for use in the United States for acromegaly. The starting dose is 90 mg subcutaneously every 4 weeks for 3 months, and then the dose is adjusted based on growth hormone and insulin-like growth factor levels.[12] Vapreotide is an orphan drug that is indicated for pancreatic and GI fistulas as well as esophageal variceal bleeding.

Miscellaneous Products

Probiotics are microorganisms given to reestablish normal colonic microflora. This supposedly restores normal intestinal function and suppresses the growth of pathogenic microorganisms. There is conflicting evidence on whether *Saccharomyces boulardii*, *Lactobacillus* GG, and *Lactobacillus acidophilus* decrease the duration of infectious and antibiotic-induced diarrhea in adults and children.[13] Probiotics may prevent antibiotic-associated diarrhea (AAD).[14] However, a randomized control trial in hospitalized patients over the age of 65 years found no difference in cases of AAD between a probiotic preparation (two strains of lactobacillus acidophilus and Bifidobacterium) and placebo.[15] The dosage of probiotic preparations varies depending on the brand used. Intestinal flatus is the primary patient complaint experienced with this modality.

Anticholinergic drugs such as atropine block vagal tone and prolong gut transit time. Drugs with anticholinergic properties are present in many nonprescription products. Their value in controlling diarrhea is questionable and limited because of side effects. Angle-closure glaucoma, selected heart diseases, and obstructive uropathies are relative contraindications to the use of anticholinergic agents.

Lactase enzyme products are helpful for patients who are experiencing diarrhea secondary to lactose intolerance. Lactase is required for carbohydrate digestion. When a patient lacks this enzyme, eating dairy products causes an osmotic diarrhea. Several products are available for use each time a dairy product, especially milk or ice cream, is consumed.

Vaccines

Vaccines are a new therapeutic frontier in controlling infectious diarrheas, especially in developing countries.[16] An oral vaccine for cholera (Vaxchora®) is licensed for use in the United States. The Advisory Committee for Immunization Practices (ACIP) recommends the vaccine for adults aged 18 to 64 years old who are traveling to an endemic area.[17] Studies in the United States suggest the vaccine can reduce the risk of severe diarrhea by about 90%, but data in endemic areas is lacking.[18]

Oral *Shigella* vaccine, although effective under field conditions, requires five weekly oral doses and repeat booster doses, thereby limiting its practicality for use in developing nations. With about 1,500 serotypes for *Salmonella*, a vaccine is not available for humans. There are two newer typhoid vaccine formulations, one a parenteral inactivated whole-cell vaccine and the other an oral live-attenuated (Ty21a) vaccine that is administered in four doses on days 1, 3, 5, and 7, to be completed at least 1 week before exposure. Two rotavirus vaccines prevent gastroenteritis due to rotavirus infection in infants and children in the United States.[19] The pentavalent human-bovine reassortant vaccine (RotaTeq from Merck) is administered as a three-oral-dose sequence, and the monovalent human vaccine (Rotarix from GlaxoSmithKline) is administered as a two-oral-dose sequence. Two additional vaccines were prequalified by the WHO in 2018 and are being utilized in India (Rotavac from Bharat Biotech and ROTASIL from Serum Institute of India pvt. ltd.).[20]

Evaluation of Therapeutic Outcomes

Therapeutic outcomes are directed toward key symptoms, signs, and laboratory studies. Constitutional symptoms usually improve within 24 to 72 hours. Monitoring for changes in the frequency and character of bowel movements on a daily basis in conjunction with vital signs and improvement in appetite are of utmost importance. Also, the clinician needs to monitor body weight, serum osmolality, serum electrolytes, complete blood cell counts, urinalysis, and culture results (if appropriate).

Acute Diarrhea

Most patients with acute diarrhea experience mild-to-moderate distress. In the absence of moderate-to-severe dehydration, high fever, and blood or mucus in the stool, this illness is usually self-limiting within 3 to 7 days. Mild-to-moderate acute diarrhea is usually managed on an outpatient basis with oral rehydration, symptomatic treatment, and diet. Older patients with chronic illness as well as infants may require hospitalization for parenteral rehydration and close monitoring.

Severe Diarrhea

In the urgent/emergent situation, restoration of the patient's volume status is the most important outcome. Toxic patients (fever dehydration, hematochezia, or hypotension) require hospitalization, IV fluids and electrolyte administration, and empiric antibiotic therapy while awaiting culture and sensitivity results. With timely management, these patients usually recover within a few days.

CONSTIPATION

5 Constipation is a common complaint among the general population and accounts for many medical visits each year in the United States.[21] It is generally defined by the American Gastroenterology Association (AGA) as difficult or infrequent passage of stool, at times associated with straining or a

feeling of incomplete defecation.[22]

Constipation may be further defined by quantitative or qualitative measures. For instance, physicians often use stool frequency to define constipation (most commonly fewer than three bowel movements per week); however, the "normal" frequency of bowel movement is not well established and can vary from person to person. Patients more often describe constipation in terms of symptoms or a combination of quantitative and qualitative descriptors that are difficult to quantify: bowel movement frequency, stool size or consistency (hard or lumpy stools), straining on defecation, inability to defecate at will, and symptoms such as sensation of incomplete evacuation. The condition is considered chronic if symptoms last for at least 3 months. Many people believe that daily bowel movements are required for normal health or that accumulation of toxic substances will occur with infrequent defecation. Inappropriate laxative use by the general public may result from these misconceptions.

Though often considered more of a minor uncomfortable or unpleasant problem, constipation can have serious consequences and be costly to the healthcare system. Patients with constipation spend approximately $8,700 more in overall medical costs compared to patients without constipation.[21]

Epidemiology

The prevalence of constipation depends on the definition used and whether the condition is self-reported or provider-diagnosed. The prevalence of chronic constipation in adults (older than or equal to 15 years old) worldwide is estimated to be 15%.[23]

Constipation is more common in women (2.4-fold more likely) and older patients.[23] Other factors associated with constipation in some reports include inactivity, resource limited populations, lower income, non-White race, symptoms of depression, and history of physical or sexual abuse.

Pathophysiology

Constipation may be primary or secondary. Primary, or idiopathic, constipation occurs without an identifiable underlying cause, whereas secondary constipation may be the result of constipating drugs, lifestyle factors, or medical disorders (Table 54-5).[23] Primary constipation can be further divided into three categories—normal transit, slow transit, and pelvic floor dysfunction, or disordered defecation.[23,24] Normal transit constipation, often referred to as functional, is the most common type. These patients have normal GI motility and stool frequency but may experience difficulty evacuating, passage of hard stools, or bloating and abdominal discomfort. Slow transit constipation represents an abnormality of GI transit time that leads to infrequent defecation. Dysfunction of the pelvic floor muscles and/or anal sphincter is the most frequently encountered reason for disordered defecation. In patients with defecatory disorders, these muscles or sphincter contract during defecation instead of relax and impede evacuation of stool. It is common for patients to have and present with more than one type of constipation.

TABLE 54-5

Possible Causes of Constipation

Conditions	Possible Causes
GI disorders	Irritable bowel syndrome
	Diverticulitis
	Upper GI tract diseases
	Anal and rectal diseases
	Hemorrhoids
	Anal fissures
	Ulcerative proctitis

	Tumors
	Hernia
	Volvulus of the bowel
	Syphilis
	Tuberculosis
	Helminthic infections
	Lymphogranuloma venereum
	Hirschsprung's disease
Metabolic and endocrine disorders	Diabetes mellitus with neuropathy
	Hypothyroidism
	Panhypopituitarism
	Pheochromocytoma
	Hypercalcemia
	Enteric glucagon excess
Cardiac disorders	Heart failure
Pregnancy	Depressed gut motility
	Increased fluid absorption from colon
	Use of iron salts
Lifestyle factors	Dietary changes
	Inadequate fluid intake
	Low dietary fiber
	Decreased physical activity
Neurogenic causes	CNS diseases
	Trauma to the brain (particularly the medulla)
	Spinal cord injury
	CNS tumors

	Cerebrovascular accidents
	Parkinson's disease
Psychogenic causes	Ignoring or postponing urge to defecate
	Psychiatric diseases
Drug induced	See Table 54-6

Factors associated with the increased prevalence of constipation in older patients include a higher number of daily medications, particularly anticholinergic agents, increased incidence of chronic comorbidities, and changes in mobility status.[25] Changes in diet such as decreased fluid and/or fiber intake, diminished physical activity, and institutionalization can lead to constipation. Physiologic changes such as mesenteric dysfunction and changes in anorectal function, including loss of rectal wall elasticity, are also thought to predispose older patients to constipation.

Drug-Induced Constipation

Use of drugs that inhibit the neurologic or muscular function of the GI tract, particularly the colon, may result in secondary constipation.[23] Medications that are commonly associated with causing constipation include opiates, anticholinergic agents, and certain antacids.[23] With most of the agents listed in Table 54-6, the inhibitory effects on bowel function may be dose dependent, with larger doses causing constipation more frequently.

TABLE 54-6

Drugs Causing Constipation

- Analgesics
- Inhibitors of prostaglandin synthesis
- Opiates
- Nonsteroidal anti-inflammatory agents
- Anticholinergics
- Antihistamines
- Antiparkinsonian agents (eg, benztropine or trihexyphenidyl)
- Phenothiazines
- Tricyclic antidepressants
- Antacids containing calcium carbonate or aluminum hydroxide
- Barium sulfate
- Calcium channel antagonists
- Clonidine
- Diuretics (non–potassium-sparing)
- Ganglionic blockers
- Iron preparations
- Muscle blockers (d-tubocurarine, succinylcholine)
- Polystyrene sodium sulfonate

Opiates have effects on all segments of the bowel, but effects are most pronounced on the colon. The major mechanism by which opiates produce constipation has been proposed to be prolongation of intestinal transit time by causing spastic, nonpropulsive contractions. Additionally, anal sphincter tone may be increased with an accompanying decrease in reflex relaxation leading to difficult rectal evacuation.[26]

While all opiate derivatives are associated with constipation, the degree of intestinal inhibitory effects seems to differ between agents. Orally administered opiates appear to have greater inhibitory effects than parenterally administered products.

Other medications may increase the risk of constipation by a variety of mechanisms. Anticholinergic agents decrease contractility of intestinal muscle while calcium channel blockers are thought to cause rectosigmoid dysfunction, leading to constipation. Nonsteroidal anti-inflammatory drugs (NSAIDs) may lead to constipation due to their inhibition of prostaglandin synthesis.[29]

Clinical Presentation

A symptom-based system for classifying functional constipation (and other functional GI disorders) is often used to define constipation in clinical trials. The Rome criteria encompass both quantitative (frequency) and qualitative (stool consistency, etc.) symptoms associated with constipation.[27] Table 54-7 outlines general clinical presentation of patients with constipation. According to the Rome IV criteria, patients should have at least two of the signs and symptoms listed in Table 54-7 apply to a minimum of 25% of bowel movements.

TABLE 54-7

Clinical Presentation of Constipation

Signs and symptoms

- Infrequent bowel movements (<3 per week)
- Stools that are hard, small, or dry
- Straining
- Feeling of incomplete evacuation
    - Feeling of anorectal obstruction or blockage
    - Physical tactics needed for defecation
    - Loose stools rarely occur without laxative use

Alarm signs and symptoms

- Hematochezia
- Melena
- Family history of colon cancer
- Family history of inflammatory bowel disease
- Anemia
- Unintentional weight loss >10% body weight
- Anorexia
- Nausea and vomiting
- Severe, persistent constipation that is refractory to treatment
- New-onset or worsening constipation in elderly without evidence of primary cause

Physical examination

- Perform rectal exam for presence of anatomical abnormalities (such as fistulas, fissures, hemorrhoids, rectal prolapse) or abnormalities of perianal descent
- Digital examination of rectum to check for fecal impaction, anal stricture, or rectal mass

Laboratory and other diagnostic tests

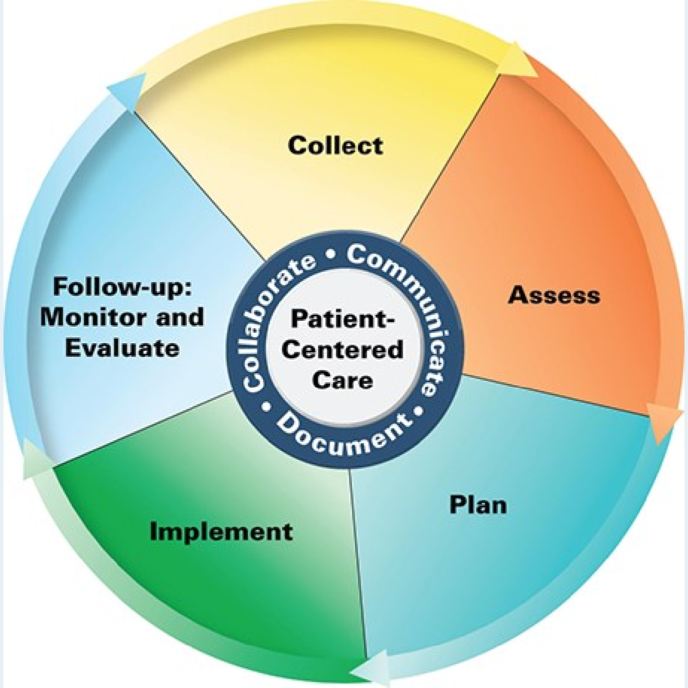
- No routine recommendations for lab testing—as indicated by clinical discretion
- In patients with signs and symptoms suggestive of organic disorder, specific testing may be performed (ie, thyroid function tests, electrolytes, glucose, complete blood count) based on clinical presentation
- In patients with alarm signs and symptoms or when structural disease is a possibility, select appropriate diagnostic studies:
    1. Rectal Balloon Expulsion Test (BET)
    2. Anorectal manometry
    3. Colonoscopy
    4. Barium defecography

Evaluation of constipation should attempt to clarify the patient's specific symptoms (ie, exactly what the patient means by constipation).[23] A complete and thorough history should be obtained from the patient, including frequency of bowel movements and duration of symptoms. Constipation occurring abruptly in an adult may indicate significant colon pathology such as malignancy. Constipation present since early infancy may be indicative of neurologic disorders. The patient should also be carefully questioned about usual diet and laxative regimens. Does the patient have a diet consistently deficient in high-fiber items and containing mainly high refined foods? What laxatives or cathartics has the patient used to attempt relief of constipation? The patient should be questioned about other concurrent medications, with interest focused on agents that might cause constipation.

Evaluation should also include perianal and anal examinations to identify fecal impaction or other anatomical obstructions that may be contributing to or causing constipation. General health status, signs of underlying medical illness (ie, hypothyroidism), and psychological status (eg, depression or other psychological illness) should also be assessed. Laboratory tests may be performed, particularly if the patient is presumed to suffer from secondary causes and is still experiencing symptoms after a trial of fiber supplementation or other nonprescription therapies.[23]

Specific attention should be given to identify any "alarm symptoms" that would warrant further diagnostic workup (see Table 54-7).[23] Patients with alarm symptoms, a family history of colon cancer, or those more than 50 years old with new symptoms may need further diagnostic evaluation.

Patient Care Process for Constipation



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics
- Patient medical, social, and family history including dietary habits
- Current medications, including nonprescription
- Vital signs and weight
- Laboratory tests depending upon medical history and other presenting symptoms
  - Thyroid function tests, complete blood count, glucose, serum electrolytes

Assess

- Underlying causes of constipation (see Tables 54-5 and 54-6)
- Presence of alarm symptoms (Table 54-7)
- Severity of symptoms
- Patient preference for symptom resolution
- Ability/willingness to pay for treatment options

Plan[*]

- Treat specific cause of constipation (ie, thyroid dysfunction)
- Dietary modification to increase fiber (Fig. 54-3)
- Laxative or cathartic option if quick resolution desired and no contraindications (Fig. 54-3; Table 54-8)
- Other pharmacologic therapy (Fig. 54-3; Table 54-8)
- Monitor symptom resolution for efficacy, and pronounced diarrhea for safety
- Patient education regarding lifestyle and dietary modifications, drug-specific information, etc.
- Referral to other providers when appropriate (unresolved symptoms or alarm symptoms present)

Implement

- Educate the patient on all aspects of the treatment plan
- Schedule follow-up to monitor safety and efficacy of treatment plan

Follow-up: Monitor and Evaluate

- Determine resolution of constipation and related symptoms
- Assess for presence of adverse effects (eg, abdominal pain, diarrhea)
- Assess patient adherence to treatment plan
- Reevaluate periodically until resolution

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

Treatment

Desired Outcome

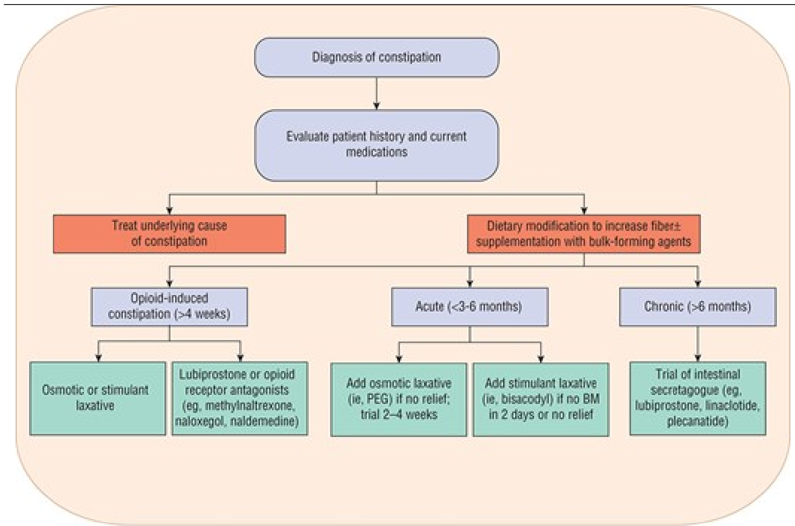
The major goals of treatment are to (a) relieve symptoms, (b) reestablish normal bowel habits, and (c) improve quality of life by minimizing adverse effects of treatment.

General Approach to Treatment

Figure 54-3 presents a general treatment algorithm for the management of constipation.

FIGURE 54-3

A general treatment algorithm for constipation.



Diagnosis of constipation
Evaluate patient history and current medications
Treat underlying cause of constipation
Dietary modification to increase fiber± supplementation with bulk-forming agents
Opioid-induced constipation (>4 weeks)
Acute (<3-6 months)
Chronic (>6 months)
Osmotic or stimulant laxative
Lubiprostone or opioid receptor antagonists (eg, methylnaltrexone, naloxegol, naldemedine)
Add osmotic laxative (ie, PEG) if no relief; trial 2–4 weeks
Add stimulant laxative (ie, bisacodyl) if no BM in 2 days or no relief
Trial of intestinal secretagogue (eg, lubiprostone, linaclotide, plecanatide)

⑥ Approaches to the treatment of constipation should begin with attempts to determine its cause. If an underlying disease is recognized as the cause of constipation, attempts should be made to correct it. Malignancies may be removed via surgical resection. Endocrine and metabolic derangements should be corrected by the appropriate methods. For example, when hypothyroidism is the cause of constipation, cautious institution of thyroid replacement therapy is the most important treatment measure. If a patient is consuming medications known to cause constipation, consideration should be given to alternative agents. If a patient must remain on constipating medications, then more attention must be given to general measures for prevention of constipation, as discussed in the next section. Also, patients with opioid-induced constipation (OIC) may require the routine use of pharmacologic agents, also discussed below.

The proper management of constipation will require a combination of nonpharmacologic and pharmacologic therapies. Osmotic laxative therapy is considered the preferred first line for the treatment of constipation, in addition to increasing dietary fiber or using fiber supplementation.[27,28] Patients are often encouraged to increase daily fluid intake and physical activity as well dedicate time to respond to the urge to defecate, although efficacy data are conflicting for these measures.[23]

Nonpharmacologic Therapy

Dietary Modification

The most important aspect of therapy for constipation for the majority of patients is dietary modification to increase the amount of fiber consumed. Fiber, the portion of vegetable matter not digested in the human GI tract, increases stool bulk, retention of stool water, and rate of transit of stool through the intestine. The result of fiber therapy is an increased frequency of defecation. Also, fiber decreases intraluminal pressures in the colon and rectum, which is thought to be beneficial for diverticular disease and for irritable bowel syndrome (IBS).

⑦ The specific physiologic effects of fiber are not well understood. Patients should be advised to gradually increase daily fiber intake to 20 to 30 g, through either dietary changes or fiber supplement products (see section “Bulk-Forming Agents“ below), a strong recommendation from the American College of Gastroenterology.[30] Fruits, vegetables, and cereals typically have the highest fiber content. Bran, a by-product of milling of wheat, is often added to foods to increase fiber content and contains a high amount of soluble fiber, which may be extremely constipating in larger doses. Raw bran is generally 40% fiber.

A trial of dietary modification with high-fiber content should be continued for at least 1 month before effects on bowel function are determined. Most patients begin to notice effects on bowel function 3 to 5 days after beginning a high-fiber diet, but some patients may require a considerably longer period of time. Patients should be cautioned that abdominal distension and flatulence may be particularly troublesome in the first few weeks of fiber therapy, especially with high bran consumption. Gradually increasing dietary fiber over a few weeks to the goal of 20 to 30 g may help reduce some of the adverse abdominal effects, as well as ensuring adequate fluid intake. In most cases these problems resolve with continued use.

Surgery

In a small percentage of patients who present with complaints of constipation, surgical procedures are necessary because of the presence of colonic malignancies or GI obstruction from a number of other causes. Patients who have slow-transit-type primary constipation that is refractory to treatment are also surgical candidates.[23,28] Surgery may be required in some endocrine disorders that cause constipation, such as pheochromocytoma, which requires removal of a tumor. In each case, the involved segment of intestine may be resected or revised.

Biofeedback

Patients with constipation due to pelvic floor dysfunction/disordered defecation may have a less favorable response to fiber therapy than other constipation subtypes.[30] Many adult patients with functional defecatory disorders appear to benefit from pelvic floor retraining with biofeedback therapy. The goals of biofeedback are to improve pelvic floor relaxation to facilitate the passage of stool and the procedure is typically performed over 4- to 6-hour-long sessions. Success rates of 65% to 80% have been reported in controlled and uncontrolled studies, and improvement has been sustained for up to 1 year. The value of biofeedback in children with chronic constipation has not been well demonstrated.

Electrical Stimulation

Sacral nerve stimulation is a minimally invasive technique that has been used for treatment of fecal incontinence and there are some reports of its use in severe refractory chronic constipation.[31] However, clinical data supporting the use of electrical stimulation for this purpose are limited and there are no recommendations for general practice.

Pharmacologic Therapy

Three general classes of laxatives are discussed in this section: (a) those causing softening of feces in 1 to 3 days; (b) those that result in soft or semifluid stool in 6 to 12 hours; and (c) those causing watery evacuation in 1 to 6 hours (Table 54-8). Other pharmacologic agents available for the treatment of constipation include a calcium channel activator, guanylate cyclase C agonist, and serotonergic agents.

TABLE 54-8

Dosage Recommendations for Pharmacologic Therapy

Agent	Recommended Dose
Agents that Cause Softening of Feces in 1-3 Days	
Bulk-forming agents	
Methylcellulose Polycarbophil Psyllium	Varies with product 4-6 g/day Varies with product
Emollients	
Docusate sodium Docusate calcium Docusate potassium	50-360 mg/day 50-360 mg/day 100-300 mg/day
Osmotic Laxatives	
Polyethylene glycol 3350 Lactulose	17 g/dose 15-30 mL orally

Lacitol Sorbitol	20 g/day orally 30-50 g/day orally
Agents that Result in Soft or Semifluid Stool in 6-12 Hours	
Bisacodyl (oral) Senna Magnesium sulfate (low dose)	5-15 mg orally Dose varies with formulation <10 g orally
Agents that Cause Watery Evacuation in 1-6 Hours	
Magnesium citrate Magnesium hydroxide Magnesium sulfate (high dose) Sodium phosphates Bisacodyl Polyethylene glycol-electrolyte preparations	18 g 300 mL water 2.4-4.8 g orally 10-30 g orally Varies with salt used 10 mg rectally 4 L
Intestinal Secretagogues	
Lubiprostone Linaclotide Plecanatide	24 mcg orally twice daily 145 mcg orally daily 3 mg orally daily
Opioid Antagonists	
Methylnaltrexone Naloxegol Naldemedine	450 mg orally daily or 12 mg subcutaneously daily 25 mg daily 0.2 mg daily
Prokinetics	
Prucalopride	2 mg daily

Bulk-Forming Agents

Medicinal products, often called "bulk-forming agents," such as psyllium hydrophilic colloids, methylcellulose, or polycarbophil, have properties similar to those of dietary fiber and may be taken as tablets, powders, or granules.[25] These agents increase the water content of stool to increase stool bulk and weight and relieve the symptoms of constipation within 3 days of initiating therapy.

Bulk-forming laxatives have few adverse effects. The most common effects include flatulence, abdominal bloating, and distention. Rarely, these agents may lead to bowel obstruction. Patients should also be cautioned to consume sufficient fluid while supplementing with bulk-forming agents to avoid obstruction of the esophagus, stomach, small intestine, and colon.

Emollient Laxatives

Emollient laxatives, including docusate in its various salts, are surfactant agents that work by facilitating mixing of aqueous and fatty materials within the intestinal tract; these are commonly referred to as stool softeners.[23,25,32] Increased stool moisture content should lead to a softer, easier-to-pass stool. These products are generally given orally, although docusate potassium has also been used rectally. With these products, softening of stools occurs within 1 to 3 days of therapy. Docusate has little evidence to support efficacy in treating constipation.[23] Although docusates are generally safe, a few adverse drug reactions have been noted.

Hyperosmolar Agents

Nonabsorbable Carbohydrates

Lactulose is a nonabsorbable disaccharide that is metabolized by colonic bacteria to low-molecular-weight acids, resulting in an osmotic effect whereby fluid is retained in the colon.[33] The fluid retained in the colon lowers the pH and increases colonic peristalsis within 2 to 3 days of use. Lactulose increases stool frequency and consistency in patients with chronic constipation (vs placebo) and may be more effective than fiber alone. In comparison to polyethylene glycol (PEG), lactulose is slightly less effective in increasing stool frequency per week and patients are more likely to need additional products for constipation relief. The most common adverse effects include flatulence, nausea, and abdominal discomfort or bloating—although lactulose can be useful in some patients. It may be justified as an alternative for acute constipation or in patients with an inadequate response to increased dietary fiber and bulking agents. In addition to the adverse abdominal effects associated with lactulose, diarrhea and electrolyte imbalances can occasionally occur. Sorbitol, a monosaccharide, also exerts its effect by osmotic action and has been recommended as a cost-effective alternative to lactulose. It is as effective as lactulose but may cause less nausea and is much less expensive.

Lactitol is a monosaccharide sugar alcohol that is approved for the treatment of chronic idiopathic constipation. The oral powder should be dissolved in four to eight ounces of a liquid beverage and taken with a meal daily. The most common adverse drug reactions are flatulence and diarrhea.[34]

Polyethylene Glycol

PEG is FDA-approved for treatment of constipation at low doses and is expected to produce a bowel movement in 1 to 3 days.[23,33] For this indication, PEG is administered in smaller volumes (10-30 or 17-34 g per 120-240 mL) usually once (or twice) daily. PEG is not absorbed systemically or metabolized by colonic bacteria, and therefore has a lower incidence of adverse effects compared with other osmotic laxatives. Daily use in low dose (17 g) may be safe and effective for up to 6 months, even in children.[35] PEG has a strong recommendation from the American College of Gastroenterology for the treatment of chronic constipation and is available as a nonprescription drug.[27] It is also preferred by the AGA if fiber supplementation is insufficient due to high efficacy based on high quality of evidence available.[28,30] The most common adverse effects are GI-related and include nausea, vomiting, flatulence, and abdominal cramping.[23] PEG solutions with electrolytes are used as bowl cleansing regimens prior to GI-related procedures, and should not be used routinely for treatment of constipation.

Magnesium Salts

Magnesium salts, including hydroxide, phosphate, and citrate, and sodium phosphate are frequently used as bowel preparations prior to diagnostic procedures such as colonoscopy.[23,32] Milk of magnesia (an 8% suspension of magnesium hydroxide), though, may be used occasionally to treat constipation in otherwise healthy adults, but efficacy data are limited. These agents should not be used on a routine basis as they may cause fluid and electrolyte depletion. Also, magnesium or sodium accumulation may occur in patients with renal dysfunction or congestive heart failure. These risks increase with long-term use.

Glycerin

Glycerin is usually administered as a suppository and exerts its effect by osmotic action in the rectum. As with most agents given as suppositories, the onset of action is usually less than 30 minutes. Glycerin is considered a safe laxative, although it may occasionally cause rectal irritation. Its use is acceptable on an intermittent basis for constipation or fecal impaction, particularly in children.[35]

Stimulant Laxatives

Stimulant laxatives such as diphenylmethane (bisacodyl) and anthraquinone (senna and others) derivates primarily affect the colon.[23] These agents stimulate the mucosal nerve plexus of the colon and may also affect intestinal fluid secretion by altering fluid and electrolyte transport, and are expected to cause a bowel movement within 8 to 12 hours of administration. Stimulant laxatives may cause severe abdominal cramping and electrolyte imbalances, particularly with chronic use. Compared with placebo, bisacodyl is effective in treatment of constipation.[30] These agents are typically reserved for intermittent use or in patients who fail to respond adequately to bulking and osmotic laxatives. Some patients, though, with severe chronic constipation and nonmodifiable risk factors may use these agents on a more regular basis.[24]

Intestinal Secretagogues

Lubiprostone

Lubiprostone is a chloride channel activator that acts locally in the gut to open chloride channels on the GI luminal epithelium, which, in turn, stimulates chloride-rich fluid secretion into the intestinal lumen. Increased intraluminal fluid secretion helps to soften stool and accelerate GI transit time.[24] Lubiprostone is FDA-approved for adults with chronic idiopathic constipation as well as treatment of patients with OIC at a recommended dose of one 24-mcg capsule twice daily with food.[24] Patients treated with lubiprostone have a significant increase in spontaneous bowel movements versus placebo as well as improvement in straining, stool consistency, and overall constipation severity.[30] For most patients, bowel movements occur within 24 to 48 hours of lubiprostone administration. Common adverse effects include nausea, headache, and diarrhea and may be dose dependent.[32] Because of its high cost (especially relative to other available laxative agents) and lack of comparative data with other laxative therapies, lubiprostone is reserved for patients with chronic constipation who fail conventional first-line agents such as osmotic laxatives and fiber supplementation, or for those with OIC.

Linaclotide

Linaclotide is approved for the treatment of constipation and constipation-predominant irritable bowel syndrome (IBS-C).[23] It is a synthetic 14-amino-acid peptide that binds to and activates the guanylate cyclase C receptor found on the intestinal epithelium. This increases intestinal fluid secretion and quickens intestinal motility. Doses of 72 mcg and 145 mcg are approved for treatment of constipation, and patients should be instructed to take linaclotide on an empty stomach at least 30 minutes before the first meal of the day. Diarrhea was the most commonly reported adverse event in clinical trials, followed by flatulence and abdominal pain. Linaclotide should not be used in patients under the age of 18.[36]

Plecanatide

Plecanatide is approved for the treatment of adults with chronic idiopathic constipation.[37] It activates the guanylate cyclase C receptor that increases intestinal fluid secretion and motility similarly to linaclotide. Plecanatide is given once daily without regard to food at a dose of 3 mg. The most common side effect is diarrhea. Plecanatide is contraindicated in patients less than 6 years of age or those with mechanical gastrointestinal obstruction, and should not be used in patients under the age of 18.

Opioid Receptor Antagonists

Alvimopan is an oral GI-specific μ-opioid antagonist approved for short-term use in hospitalized patients to accelerate recovery of bowel function after large or small bowel resection.[38] It antagonizes the GI (peripheral) effects of opioids without affecting analgesia because it does not cross the blood–brain barrier. Alvimopan is only available through a special use program (ENTEREG access support and education [EASE]), which requires hospitals to register and meet all requirements before the drug can be administered. Additionally, alvimopan is contraindicated in patients receiving therapeutic doses of opioids for more than seven consecutive days prior to surgery as they may be more sensitive to the drug's effects. Dosing for alvimopan is as follows: 12-mg capsule administered 30 minutes to 5 hours before surgery and then 12 mg twice daily for up to 7 days or until discharge (maximum of 15 doses).

Methylnaltrexone is μ-receptor antagonist approved for OIC in patients with advanced disease receiving palliative care or when response to laxative therapy has been insufficient for patients with OIC with chronic noncancer pain.[26,38] This agent does not cross the blood–brain barrier or antagonize analgesia; it acts on peripheral μ-receptors to block unwanted opioid side effects such as constipation. It is administered at a weight-based dose as a subcutaneous injection in patients with advanced illness, usually every other day (no more than once daily). For patients with noncancer pain, methlynaltrexone can be given as a 12-mg subcutaneous injection or 450-mg oral dose daily. Laxative use should be discontinued upon initiation of methlnaltrexone, and its use is contraindicated in patients with known or suspected GI obstruction. Patients with reduced creatinine clearance (<60 mL/min [1 mL/s]) or moderate-to-severe hepatic impairment should receive reduced dosing of methlnaltrexone (ie, 150 mg orally or 6 mg subcutaneously).

Naloxegol is approved by the FDA for the treatment of OIC in adult patients with noncancer pain.[39] It is an oral pegylated naloxone molecule and antagonizes the µ-receptor. Pegylation reduces naloxegol's passive permeability of the blood–brain barrier. The recommended dose is 25 mg by mouth once daily, 1 hour before or 2 hours after a meal. The dose should be reduced by half in patients with diminished renal function (CrCl <60 mL/min [1 mL/s]) or in those unable to tolerate 25 mg. The most common side effects are abdominal pain, diarrhea, and nausea. In clinical trials, naloxegol significantly increased the number and frequency of bowel movements compared to placebo at 12 weeks.[38]

Naldemedine is a peripherally acting opioid antagonist approved for treatment of OIC in patients with chronic noncancer pain.[26] The recommended dose is 0.2 mg by mouth once daily, and there are no dose adjustments for renal or hepatic impairment. However, patients with severe hepatic impairment (ie, Child-Pugh class C) should not use naldemedine. The most common adverse effects are abdominal pain and diarrhea. Naldemedine increased the frequency of bowel movements compared to placebo in clinical trials.[26]

Other Agents

Prucalopride is a selective 5-hydroxytryptamine-4 (5-HT_4) receptor agonist approved for treatment of chronic constipation in the United States and Europe.[40] It demonstrates proenterokinetic effects (increased colonic motility and transit), specifically in the GI tract. Prucalopride is more selective than the previously available serotonergic agonists cisapride and tegaserod with higher affinity for the 5-HT_4 receptor. Receptor selectivity is thought to improve the safety profile of prucalopride over cisapride and tegaserod, which were removed from the market due to concerns for adverse cardiovascular events. In clinical trials, prucalopride significantly increased the number of complete, spontaneous bowel movements in adults with chronic constipation. Constipation symptoms and quality of life were also improved with prucalopride. This agent has been safely tolerated in clinical trials with no adverse cardiovascular effects versus placebo (although data are limited).

Probiotics may be useful in the treatment of constipation. Several randomized controlled trials conducted in children and adults revealed that certain strains of probiotics increased weekly stool frequency.[30] However, these trials were small (370 patients total) and only slight improvement was realized (one additional stool per week). More studies are needed to strengthen evidence involving probiotics, but these may be an option for patients seeking alternative treatment.[23]

Prevention

For patients recovering from myocardial infarction (MI) or rectal surgery, straining at defecation should be avoided. The basis of preventive therapy in these patients should be bulk-forming laxatives or PEG. Additionally, the use of docusate is popular, although its effectiveness is debated. In pregnant patients, constipation may result because of alterations in hormones or iron supplementation.

Evaluation of Therapeutic Outcomes

The ultimate goal of treatment for constipation is to prevent further episodes of constipation. Short-term goals include alleviation of acute constipation with relief from symptoms. For patients with chronic constipation, the goals include use of proper diet and decreased reliance on laxatives in addition to relief of symptoms for the patient so that quality of life is not diminished. Effective treatment of constipation requires the patient to become more knowledgeable about the causes of constipation, proper diet, and appropriate use of laxatives.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome is a GI syndrome that is the most commonly diagnosed GI condition, and is characterized by chronic abdominal pain and altered bowel habits in the absence of any organic cause.

Epidemiology

The prevalence of IBS is approximately 10% to 12% based on North American population-based studies; however, there is a wide variation in prevalence by individual country.[41] IBS affects men and women, young and older patients, with an overall 2:1 female predominance in North America.[42] However, younger patients and women are more likely to be diagnosed with IBS, and IBS has been linked with reduced quality of life.[41,43]

Pathophysiology

Although the exact pathophysiologic abnormalities with IBS are still being actively investigated, IBS likely results from altered somatovisceral and motor dysfunction of the intestine from a variety of causes. Abnormal CNS processing of afferent signals may lead to visceral hypersensitivity, with the specific nerve pathway affected determining the exact symptomatology expressed. This visceral hypersensitivity is a neuroenteric phenomenon that is independent of motility and psychological disturbances.[44] Factors known to contribute to these alterations include genetics, motility factors, inflammation, colonic infections, mechanical irritation to local nerves, stress, and other psychological factors.

The enteric nervous system contains a significant percentage of the body's 5-HT receptors.[45] Two types of 5-HT receptors exist within the gut: serotonin type 3 (HT_3) and serotonin type 4 (HT_4), which are responsible for secretion, sensitization, and motility. There is an increase in the postprandial levels of 5-HT in the GI tract in those diagnosed with diarrhea-predominant IBS compared to those who are not.[45] Therefore, stimulation and antagonism of these 5-HT receptors have become a focused area for research on new drug therapies for both diarrhea- and constipation-predominant diseases.

Clinical Presentation

8 Irritable bowel syndrome presents as either diarrhea- or constipation-predominant disease and can be defined as lower abdominal pain, disturbed defecation (constipation, diarrhea, or an alternating pattern of both), and bloating in the absence of structural or biochemical factors that might explain these symptoms (Table 54-9). Table 54-10 provides the diagnostic criteria for the Rome IV symptom-based criteria.[43]

TABLE 54-9

Clinical Presentation of Irritable Bowel Syndrome

Signs and symptoms

- Lower abdominal pain
- Abdominal bloating and distension
- Diarrhea symptoms, >3 stools/day
- Extreme urgency
- Passage of mucus
- Constipation symptoms, <3 stools/week, straining, incomplete evacuation
- Psychological symptoms such as depression and anxiety

Non-GI symptoms

- Urinary symptoms
- Fatigue
- Dyspareunia

Other concurrent conditions

- Fibromyalgia
- Functional dyspepsia
- Chronic fatigue syndrome
- Reduced health-related quality of life

TABLE 54-10

Rome IV Diagnostic Criteria for Irritable Bowel Syndrome

Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with two or more of the following:

1. Relieved with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

Data from Reference 43.

Additional diagnostic steps that can be taken include testing for fecal lactoferrin and C-reactive protein to rule out inflammatory bowel disease and serologic testing to rule out celiac disease.[43] Routine colonoscopy, examination of the stool for occult blood and ova and parasites, or testing for food allergies are not recommended.

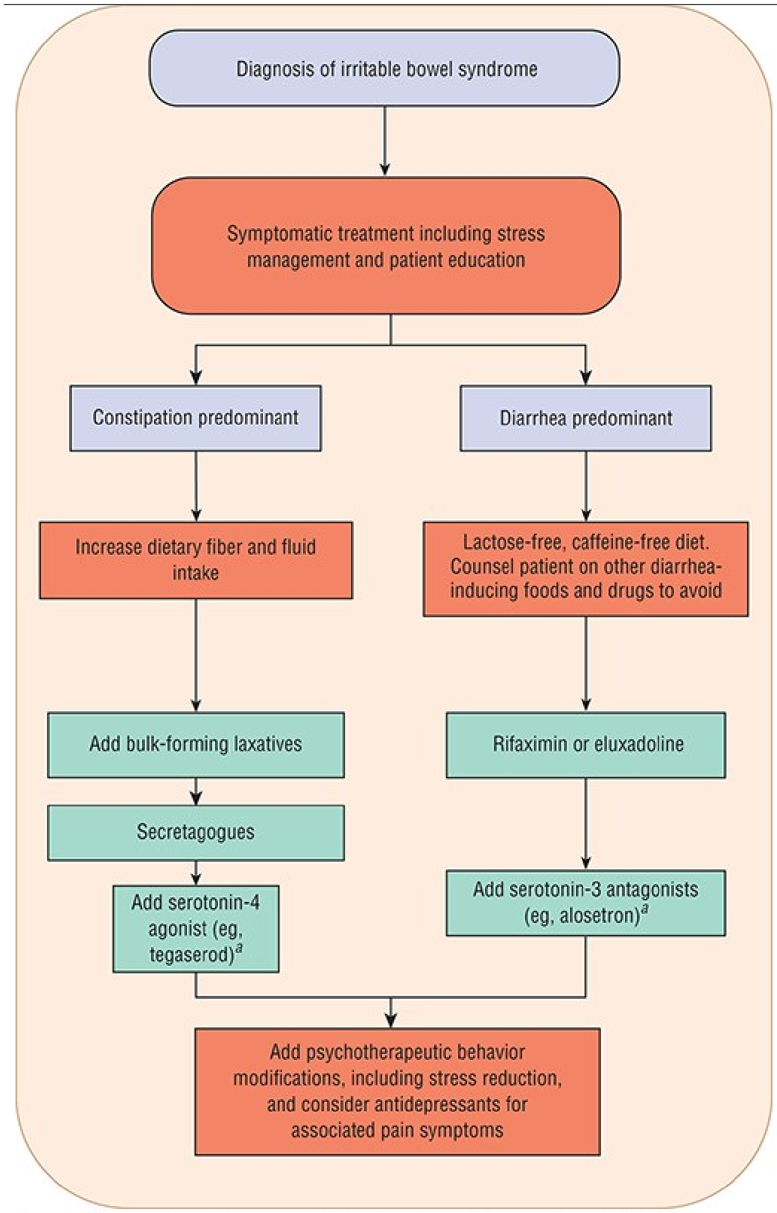
Treatment

General Approach to Treatment

The treatment approach to IBS is based on the predominant symptoms and their severity (Fig. 54-4). Exercise and a limited trial of a diet with reduced fermentable oligosaccharides, disaccharides, and monosaccharides, and polyols (FODMAPs) are recommended for overall symptom improvement.[41] More persistent disease may require pharmacologic agents, such as secretagogues, rifaximin, or eluxadoline.

FIGURE 54-4

A general stepwise approach to the management of both constipation- and diarrhea-predominant irritable bowel syndrome. [a]Consider manufacturer-sponsored patient access program.



Diagnosis of irritable bowel syndrome
Symptomatic treatment including stress management and patient education
Constipation predominant
Diarrhea predominant
Increase dietary fiber and fluid intake
Lactose-free, caffeine-free diet. Counsel patient on other diarrhea-inducing foods and drugs to avoid
Add bulk-forming laxatives
Rifaximin or eluxadoline
Secretagogues
Add serotonin-4 agonist (eg, tegaserod)a
Add serotonin-3 antagonists (eg, alosetron)a
Add psychotherapeutic behavior modifications, including stress reduction, and consider antidepressants for associated pain symptoms

Constipation-Predominant Disease

In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with one tablespoonful of fiber with one meal daily and gradually increase the dose to include fiber with two and three meals a day until the desired outcome is achieved. End points that the patient should aim for include bulkier and more easily passed stools. For patients unable to tolerate dietary bran, bulking agents such as psyllium may be substituted.[46] PEG laxatives may be used; however, the AGA does not recommend its use for global symptom relief.[43] When lifestyle modifications alone do not control symptoms, intestinal secretagogues such as linaclotide (290 mcg daily), plecanatide (6 mg daily), and lubiprostone (8 mcg twice daily) should be recommended.[41]

The 5-HT_4 partial agonist tegaserod is approved specifically for short-term, intermittent treatment of IBS-C in women.[43] Tegaserod is available in the United States through a restricted-access program due to a small, yet significant, increase in ischemia events (MI, cerebrovascular accident [CVA], and unstable angina) in patients with preexisting cardiovascular disease and/or cardiovascular risk factors. It is given as 2- or 6-mg doses given twice daily

30 minutes prior to a meal with water for up to 12 weeks. Stimulation of the 5-HT_4 receptors by tegaserod increases gastric secretions and promotes motility, with improvement in symptoms generally occurring within the first week of therapy. Diarrhea was the most common adverse effect, resulting in drug discontinuation in 1.6% of study subjects.

Diarrhea-Predominant Disease

⑨ For patients in whom diarrhea is the primary complaint, avoidance of certain food products may be necessary. Caffeine, alcohol, and artificial sweeteners (sorbitol, fructose, and mannitol) are known to irritate the gut and produce a laxative effect. Lactose intolerance should be considered in certain patients; however, the prevalence of this condition may be exaggerated.

Herbal medicines or teas often contain senna, which may produce diarrhea. In patients with disease persistence following dietary modification, loperamide may be used for episodic management of urgent diarrhea, or in situations in which the patient wishes to avoid the possibility of an acute onset of symptoms.[42] Loperamide decreases intestinal transit, enhances water and electrolyte absorption, and strengthens rectal sphincter tone. However, loperamide is not likely to address other symptoms of IBS such as abdominal pain.[43]

Diarrhea-predominant IBS caused by excessive stimulation of the 5-HT_3 receptor can be relieved by the drug alosetron, a 5-HT3-receptor antagonist. Its use is limited to an FDA-approved restricted-use program, and requires extensive postmarketing surveillance due to association with serious adverse effects, including severe constipation and ischemic colitis.[42] Additional information can be found at http://www.lotronex.com. It is indicated for women with diarrhea-predominant symptoms of longer than 6 months' duration that are not relieved by conventional therapy at a dose of 0.5 mg twice daily.

Other agents, eluxadoline and rifaximin, are approved and recommended for use in IBS-D.[43] Rifaximin is a rifamycin antibacterial indicated for the treatment of travelers' diarrhea that is indicated for the treatment of IBS-D in adults based on several randomized control trials demonstrating improvement in abdominal pain, stool consistency, and bloating.[42,47] The recommended dose is 550 mg orally three times a day for 2 weeks. Recurrences may be retreated up to two times; however, there is no evidence to support repeating the regimen. Eluxadoline is a μ-opioid receptor agonist indicated for adults with IBS-D. The recommended dose is 100 mg orally twice a day with food. A lower dose of 75 mg twice daily is recommended for patients who cannot tolerate the 100 mg dose and if they have hepatic impairment; eluxadoline should be avoided in patients without a gallbladder.[48] Its main benefits are improvement in abdominal pain and stool consistency. The main side effect seen is constipation.

Use of Antidepressants in Irritable Bowel Syndrome

Tricyclic antidepressants have some benefit in treatment of diarrhea-predominant IBS associated with moderate-to-severe abdominal pain, by modulating perception of visceral pain, altering GI transit time, and treating underlying comorbidities.[49,50] Selective 5-HT reuptake inhibitors (SSRI), fluoxetine, citalopram, and paroxetine have been studied, but the results are conflicting. Large randomized control trials lasting longer than 3 months are needed to determine the place of SSRIs in therapy.[51]

Duloxetine, a serotonin-norepinephrine reuptake inhibitor, has been used in the management of IBS with comorbid generalized anxiety disorder and major depressive disorder. Although the effect was gradual over 12 weeks, both symptom severity and quality of life significantly improved.[52,53]

Pain in Irritable Bowel Syndrome

⑩ Some patients with IBS suffer significant pain associated with their disease. Data supporting the use of antispasmodic agents in these patients are conflicting, and these are not recommended for global IBS symptoms.[43] A trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and 5-HT reuptake inhibitors produce analgesia and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response. Tricyclic antidepressants should be avoided in patients with pain and constipation. In addition, psychotherapy, including cognitive behavioral therapy, relaxation therapy, and hypnotherapy, decreases IBS symptoms.[41]

Evaluation of Therapeutic Outcomes

Irritable bowel syndrome is usually classified as constipation-predominant, diarrhea-predominant, or IBS with mixed symptoms, or unclassified. Therapeutic goals in IBS should focus on the patient's primary complaint. Additionally, global symptoms may be treated with antidepressants, relaxation/stress management, cognitive behavior treatment, and/or hypnosis aimed at specific affective disorders.[41] Lastly, the 5-HT receptor agonists and antagonists can be used in carefully selected patients whose symptoms are not adequately controlled with other agents.

ABBREVIATIONS

AAD	antibiotic-associated diarrhea
AGA	American Gastroenterology Association
AIDS	acquired immune deficiency syndrome
ATPase	adenosine triphosphatase
CDC	Centers for Disease Control and Prevention
CVA	cerebrovascular accident
EASE	ENTEREG access support and education
5-HT	serotonin

SELF-ASSESSMENT QUESTIONS

1. Most cases of acute diarrhea in the United States are due to:

A. Diabetes.

B. Food and waterborne organisms.

C. AIDS.

D. Prescription medications.

2. This type of diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of water and electrolytes:

A. Osmotic

B. Exudative

C. Secretory

D. Transitory

3. Which statement about acute diarrhea is TRUE?

A. It is self-limiting, usually subsiding within 72 hours.

B. It is secondary to diseases such as diabetes.

C. It is treatable with bulk-forming laxatives.

D. It is a chronic condition that waxes and wanes throughout life.

4. Which of the following is advocated for prevention of traveler's diarrhea?

A. Drinking water and eating fresh vegetables as much as possible while traveling

B. Use of Bismuth subsalicylate (BSS) as needed

C. Avoidance of meat products

D. Taking loperamide around the clock for 48 hours prior to travel

5. If diarrhea occurs, an appropriate treatment approach is to:

A. Increase fluid intake.

B. Stop prescription medications.

C. Withhold food.

D. Administer antibiotics until symptoms resolve.

6. This antisecretory agent used to treat diarrhea may interact with anticoagulants, interfere with tetracycline absorption, and interfere with some GI radiographic studies:

A. Polycarbophil

B. Bismuth subsalicylate

C. Loperamide

D. Diphenoxylate with atropine

7. Which of the following statements about constipation is TRUE?
    - A. Patients often describe constipation in measures that are easily quantified.
    - B. Daily bowel movements are required for health and well-being.
    - C. Decreased fiber intake can lead to constipation.
    - D. Normal healthy subjects pass at least six stools per week.
8. Possible medical causes of constipation include:
    - A. Osteoporosis.
    - B. Hypothyroidism.
    - C. Inflammatory bowel syndrome.
    - D. Hypertension.
9. The cornerstone of therapy in the treatment of constipation should include:
    - A. Decrease in fluid intake.
    - B. Increase in dietary fiber.
    - C. Biofeedback therapy.
    - D. Stimulant laxatives.
10. Which laxative is preferred first line for treatment of constipation in most patients?
    - A. Cascara sagrada
    - B. Bisacodyl
    - C. Polyethylene glycol
    - D. Glycerin
11. To prevent constipation, patients should be advised to include this amount of fiber in their daily diet:
    - A. 10 to 15 g
    - B. 20 to 25 g
    - C. 50 to 55 g
    - D. 100 to 110 g
12. For patients with opioid-induced constipation, which of the following medications can only be administered in the hospital for short-term use?
    - A. Alvimopan
    - B. Lubiprostone
    - C. Methylnaltrexone

D. Naloxegol

13. Which of the following treatment measures is recommended in constipation-predominant IBS?

A. Saline cathartics

B. Loperamide

C. Mineral oil

D. Dietary fiber

14. In addition to avoidance of certain food products, which of the following treatments is recommended in diarrhea-predominant IBS?

A. Saline cathartics

B. Rifaximin

C. Loperamide

D. Dietary fiber

15. Which of the following medications may be used for their analgesic effects in patients suffering from IBS-associated pain?

A. Amitriptyline

B. Bupropion

C. Hyoscyamine

D. Loperamide

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Common causes of acute diarrhea in the United States are food and waterborne organisms. The specific bacterial organisms are listed under the epidemiology section of diarrhea.

2. **C.** Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. See pathophysiology of "Diarrhea" section.

3. **A.** Most acute diarrhea is self-limiting, subsiding within 72 hours. The prognosis for chronic diarrhea depends on the cause; for example, diarrhea secondary to diabetes mellitus waxes and wanes throughout life. Bulk-forming laxatives are a treatment option for constipation, not diarrhea. See clinical presentation of "Diarrhea" section.

4. **B.** Antibiotics and bismuth subsalicylate are advocated to prevent traveler's diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables. It is not recommended to withhold food during acute episodes of diarrhea. Loperamide may be used to treat traveler's diarrhea; however, there is no data to support its use prophylactically. See treatment of "Diarrhea" section.

5. **A.** If prevention is unsuccessful and diarrhea occurs, the primary therapeutic goal is to prevent excessive water, electrolyte, and acid–base disturbances by increasing fluid intake. Withholding food, giving antibiotics, or stopping prescription medications are not appropriate recommendations. See treatment of "Diarrhea" section.

6. **B.** Bismuth can potentiate the effects of anticoagulants, can reduce tetracycline absorption, and may interfere with select GI radiographic studies.

7. **C.** A healthy number of stools per week can vary person to person, and measures used to describe constipation may be difficult to quantify. A lack of fiber in the diet can lead to constipation, and castor oil should be avoided due to risks. See "Constipation" section of text, and treatment algorithm.

8. **B.** Hypothyroidism is associated with constipation. See Tables 54-5.

9. **B.** Increasing fiber should be the first step in treating constipation. See treatment algorithm.

10. **C.** Due to its efficacy and fewer adverse effects, polyethylene glycol is the preferred laxative for most patients. See treatment algorithm and pharmacologic treatment in text.

11. **B.** The American College of Gastroenterology recommends increasing dietary fiber to 20 to 30 g/day. See treatment text.

12. **A.** Alvimopan is only for short-term use in the inpatient setting. See pharmacologic text.

13. **D.** In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with one tablespoonful of fiber with one meal daily and gradually increase the dose to include fiber with two and three meals a day until the desired outcome is achieved

14. **B.** In diarrhea-predominant IBS, rifaximin is recommended because it can improve abdominal pain, stool consistency, and bloating, whereas loperamide may be used for episodic management of urgent diarrhea. Loperamide is unlikely to improve other symptoms.

15. **A.** A trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and 5-HT reuptake inhibitors produce analgesia and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response.

Chapter 55: Portal Hypertension and Cirrhosis

Julie M. Sease

KEY CONCEPTS

KEY CONCEPTS

①Cirrhosis is a severe, chronic, potentially irreversible disease associated with significant morbidity and mortality. The progression of cirrhosis secondary to alcohol intake, both in those with alcoholic cirrhosis and cirrhosis due to other causes, can be interrupted by abstinence from alcohol. It is therefore imperative for the clinician to educate and support abstinence from alcohol as part of the overall treatment strategy of the underlying liver disease.

②Patients with cirrhosis, except those screened and considered to be at low risk, should receive endoscopic evaluation looking for the presence of varices. Patients with medium to large varices, or small varices with risk factors, should receive primary prophylaxis with nonselective β-adrenergic blockade therapy to prevent variceal hemorrhage.

③When nonselective β-adrenergic blocker therapy with propranolol or nadolol is used to prevent rebleeding, therapy should be titrated to achieve a goal heart rate of 55 to 60 beats/min, but systolic blood pressure must also be maintained above 90 mm Hg.

④Octreotide is the preferred vasoactive agent for the medical management of variceal bleeding in the United States. Endoscopic band ligation is the primary therapeutic tool for the management of acute variceal bleeding.

⑤The combination of spironolactone and furosemide is recommended by clinical guidelines in the United States as the initial diuretic therapy for patients with ascites.

⑥All patients who have survived an episode of spontaneous bacterial peritonitis (SBP) should receive long-term antibiotic prophylaxis.

⑦The mainstay of treatment of hepatic encephalopathy (HE) involves therapy to lower blood ammonia concentrations and includes diet modifications, lactulose, and rifaximin alone or in combination with lactulose.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the short Medscape video “Cirrhosis Overview Clinical Presentation” (https://www.youtube.com/watch?v=XJQn8MXnTWg). This video reviews the basic pathophysiology of cirrhosis and connects it to the most common complications of decompensated cirrhosis. Create a summary table of treatment options for each complication associated with decompensated cirrhosis: portal hypertension (primary prophylaxis against bleeding, acute bleeding, and secondary prophylaxis against bleeding), ascites, spontaneous bacterial peritonitis (SBP) (acute treatment and secondary prophylaxis), and hepatic encephalopathy. Use the below table as a guide.

Complication	Treatment/drug of choice (to include dose, route, and frequency)	Common adverse effects	Monitoring parameters	Patient counseling points/pharmacy pearls
Portal Hypertension Primary prophylaxis against bleeding Acute bleeding Secondary prophylaxis of bleeding				
Ascites				
SBP Acute treatment Secondary prophylaxis				
Hepatic encephalopathy				

INTRODUCTION

Chronic liver injury causes damage to normal liver tissue resulting in the development of regenerative nodules surrounded by dense fibrotic material, which are diagnostic hallmarks of cirrhosis.[1] The distorted architecture of the cirrhotic liver impedes portal blood flow, interferes with hepatocyte perfusion, and disrupts hepatic synthetic functions such as the production of albumin. Clinical consequences of cirrhosis include increased intrahepatic resistance leading to portal hypertension, varices, and variceal bleeding; ascites; infection; encephalopathy; and hepatocellular carcinoma. When advanced, cirrhosis can also lead to the development of both renal and pulmonary dysfunction.

① While cirrhosis has many causes (Table 55-1),[1–3] in industrialized countries, primary etiologies include hepatitis C, excessive alcohol intake, and nonalcoholic fatty liver disease.[1,2] Treatment strategies for managing the most commonly encountered clinical complications of cirrhosis are discussed. Fibrosis, even significant enough to have caused cirrhosis, is known to regress when anti-viral therapy for hepatitis B and C is instituted.[1] The reader is referred to Chapter 58, “Viral Hepatitis” for a detailed discussion of the treatment of cirrhosis secondary to hepatitis.

TABLE 55-1

Etiology of Cirrhosis

Alcoholism
Chronic hepatitis C
Metabolic liver disease
  Hemochromatosis
  Wilson disease
  Nonalcoholic fatty liver disease
Immunologic disease
  Autoimmune hepatitis
  Primary biliary cirrhosis
  Primary biliary cholangitis
Vascular disease
  Budd–Chiari
Drug-induced liver injury (below list not all-inclusive)

Isoniazid, macrolides, amoxicillin-clavulanate, nitrofurantoin, fluoroquinolones, amiodarone, nonsteroidal anti-inflammatory drugs, allopurinol, sulfasalazine, methotrexate, interferon-β, interferon-α, anti-tumor necrosis factor inhibitors, valproate, lamotrigine, phenytoin, carbamazepine, green tea extract

Data from References 1,2,3.

EPIDEMIOLOGY

Chronic liver disease and cirrhosis were responsible for nearly 42,838 deaths in America in 2018 making it the 11th leading cause of death.[4] Acute variceal bleeding and spontaneous bacterial peritonitis (SBP) are among the immediately life-threatening complications of cirrhosis. Associated conditions causing significant morbidity include ascites and hepatic encephalopathy (HE).

PATHOPHYSIOLOGY OF CIRRHOSIS

Any discussion of cirrhosis must be based on a firm understanding of hepatic anatomy and vascular supply. Conceptually, the liver can be thought of as an elaborate blood filtration system receiving blood from the hepatic artery and the portal vein (Fig. 55-1), with portal blood originating from the small intestines.[5] Blood enters the liver via the portal triad, which contains branches of the portal vein, hepatic artery, and bile ducts. It then drains through the sinusoidal space (also known as the space of Disse) of the hepatic lobule (Fig. 55-2), which is lined by the workhorses of the liver, the hepatocytes. Individual hepatocytes are arranged in plates that are one cell thick and organized around individual central veins. The six or more surfaces of each individual hepatocyte make contact with adjacent hepatocytes, border the bile canaliculi, or are exposed to the sinusoidal space. Filtered blood travels into the terminal hepatic venules, also called central veins, and then empties into larger hepatic veins and eventually into the inferior vena cava. There are functional gradients of hepatocytes based on oxygen saturation. Hepatocytes closest to the portal triad, which contains the hepatic artery, have greater oxygen saturation than those hepatocytes nearer to the terminal hepatic venule. Blood flows past hepatocytes in zone one, then zone two, and finally zone three before entering the central vein. Hepatocytes in zone one are involved in gluconeogenesis, urea synthesis, and oxidative energy metabolism while those in zone three carry out the functions of glycolysis and lipogenesis.

Hepatic stellate cells (HSCs), located in the space of Disse and surrounded by hepatocytes and endothelial cells, are the cell type primarily responsible for the formation of liver fibrosis.[6] Normally, HSCs function to store vitamin A and maintain the normal matrix of the sinusoidal space. Quiescent HSCs become proliferative and transform into myofibroblasts when they are stimulated to do so by hepatocytes, Kupffer cells, platelets, leukocytes, and sinusoidal endothelial cells in reaction to exposure to toxic agents, viruses, or other insults. As myofibroblasts, HSCs lose the ability to store retinoids and upregulate synthesis of extracellular matrix components. When pro-fibrogenic triggers are persistently present, excessive extracellular matrix components accumulate which alter the liver's architecture, reduce its elasticity, and impact the flow of blood through the liver which leads to elevated sinusoidal pressure and portal hypertension, hallmarks of cirrhosis.

Portal hypertension leads to changes in the splanchnic vasculature and circulation.[7] Splanchnic vasodilation and the formation of new blood vessels contribute to an increased splanchnic blood flow, formation of gastroesophageal varices, and variceal bleeding. Additionally, splanchnic and systemic vasodilation leads to hypoperfusion of the renal system that causes activation of the renin-angiotensin-aldosterone system and the sympathetic nervous system which subsequently result in functional renal impairment as well as sodium and water retention presenting as ascites.[8] Therein lies the pathophysiology of ascites and renal dysfunction that often accompany chronic liver disease. Portosystemic shunting may also occur and is involved in HE and other complications.[7]

ANATOMIC AND PHYSIOLOGIC EFFECTS OF CIRRHOSIS

Cirrhosis and the pathophysiologic abnormalities that cause it result in the commonly encountered problems of ascites, portal hypertension, esophageal varices, HE, and coagulation disorders. Other less common problems in patients with cirrhosis include hepatorenal syndrome, hepatopulmonary syndrome, and endocrine dysfunction. These are discussed under section "Management of Portal Hypertension and Variceal Bleeding."

Ascites

Ascites is the accumulation of an excessive amount of fluid within the abdomen. It is the most common major complication of cirrhosis with approximately 20% of patients presenting with ascites at the time of their cirrhosis diagnosis.[9] As noted above, portal hypertension activates vasodilatory mechanisms leading to splanchnic and systemic vasodilation and a resultant drop in mean arterial pressure.[8] Portal hypertension is also thought to lead to bacterial translocation of gut bacteria causing local and systemic inflammation and the generation of vasodilatory nitric oxide and prostacyclins in the splanchnic vasculature which further reduces mean arterial pressure. This drop in mean arterial pressure is recognized by arterial baroreceptors activating endogenous vasoconstrictor systems including the sympathetic nervous system, the renin-angiotensin-aldosterone system, as well as a nonosmotic vasopressin release.[10] Renal vasoconstriction and sodium and water retention ensue resulting in the formation of edema and ascites. The excess fluid shifts from the intravascular compartment into the abdominal cavity. Hypoalbuminemia, which results from the decreased synthetic function of the diseased liver, contributes further to fluid leakage into the abdomen. The end result of this complex process is the sustained peritoneal ascites of end-stage liver disease (Fig. 54-3).

Portal Hypertension and Varices

Sinusoidal portal hypertension is most often caused by cirrhosis.[11] It is associated with acute variceal bleeding, a medical emergency that is among the most severe complications of cirrhosis.[12] Portal hypertension is defined by the presence of a gradient of greater than 5 mm Hg (0.7 kPa) between the portal and central venous pressures (see Fig. 55-1).[11] This gradient is called the hepatic venous pressure gradient (HVPG). Esophageal and gastric varices and variceal bleeding may arise after an HVPG pressure gradient of 10 mm Hg (1.3 kPa) is reached.

Progression to bleeding can be predicted by Child-Pugh score, size of varices, and the presence of red wale markings on the varices. First variceal hemorrhage occurs at an annual rate of about 15% and carries a mortality of 7% to 15%. Rebleeding is common following initial hemorrhage with a median rate of 60% and carries a mortality rate as high as 33%. Prevention of bleeding is a major goal in the therapy of portal hypertension, and strategies include both pharmacologic and surgical approaches.

Hepatic Encephalopathy

Hepatic encephalopathy is a functional disturbance of the brain caused by liver insufficiency or portal systemic shunting that presents on a wide spectrum of symptom severity ranging from subclinical alterations to coma.[13] Symptoms of HE result from an accumulation of gut-derived nitrogenous substances in the systemic circulation as a consequence of decreased hepatic functioning.[14] Once these substances enter the CNS, they cause alterations of neurotransmission that affect consciousness and behavior. Ammonia is the most commonly cited culprit in the pathogenesis of HE, but glutamine, benzodiazepine receptor agonists, and aromatic amino acids are also potential causes.[13,14] Arterial ammonia levels are commonly increased in both acute and chronic liver diseases, but an established correlation between blood ammonia levels and mental status does not exist.[14] A normal ammonia level finding brings the diagnosis of HE into question.[13] Interventions to lower blood ammonia levels remain the mainstay of treatment for HE.[13,14]

Hepatic encephalopathy is categorized as type A, B, or C.[13] Type A is HE induced by acute liver failure, type B is due to portal-systemic bypass without associated intrinsic liver disease, and type C is HE that occurs in patients with cirrhosis. The severity of HE symptoms, time course (whether episodic, recurrent, or persistent), and whether incited by precipitating factors (such as infection, GI bleeding, an electrolyte disorder, or constipation) are additional ways in which HE is classified. The majority of episodic cases of HE secondary to cirrhosis are associated with a precipitant. It is important that precipitating factors be sought and treated when present.

Coagulation Defects

End-stage chronic liver disease is associated with decreased synthetic capability of the liver leading to decreased levels of most procoagulant factors as well as the naturally occurring anticoagulants, antithrombin, protein C, and protein S.[15] However, two procoagulant factors, factor VIII and von Willebrand factor, are actually elevated in chronic liver disease. It was thought that chronic liver disease induced an acquired bleeding disorder owing to the decrease in most procoagulant factors, but it is now believed that these patients actually live in a tenuous state of rebalanced hemostasis. This is due to increased levels of factor VIII and von Willebrand factor and the decreased levels of natural anticoagulants (antithrombin, protein C, and protein S). The rebalanced homeostasis seen in chronic liver disease can be tipped toward either thrombosis or clinically significant bleeding at any time depending on the circumstances experienced by the patient at the time. The prothrombin time (PT) is a standard component of the Child-Pugh scoring system and the international normalized ratio (INR) is utilized in the model for end-stage liver disease, a prognostic evaluation tool. The ability of the PT and INR to accurately measure bleeding risk and assist with estimation of the severity of a patient's liver disease has been called into question.[15]

Both platelet number and function may be affected in cirrhosis. Thrombocytopenia, a common finding in cirrhosis, could promote bleeding. However, von Willebrand factor, the binding site for platelets, is not decreased by cirrhosis and thrombin generation assays show that platelet procoagulant activity is actually preserved in patients with cirrhosis. Fibrinolysis is another process that is likely rebalanced in cirrhosis. While α-2-antiplasmin and thrombin-activatable fibrinolysis inhibitor levels are reduced, tissue plasminogen activator levels are increased. These changes would be expected to increase the risk for bleeding. However, procoagulant changes, including reduced plasminogen levels and normal to increased platelet activator inhibitor levels, occur concurrently, which provide a homeostasis in the fibrinolysis process.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Cirrhosis

Signs and Symptoms

- Asymptomatic
- Splenomegaly
- Jaundice, palmar erythema, and spider nevi
- Gynecomastia
- Ascites and edema
- Malaise, anorexia, and weight loss
- Encephalopathy

Laboratory Tests

- Hypoalbuminemia
- Elevated prothrombin time (PT)
- Thrombocytopenia
- Elevated alkaline phosphatase
- Elevated aspartate transaminase (AST), alanine transaminase (ALT), and γ-glutamyl transpeptidase (GGT)

CLINICAL PRESENTATION: Portal Hypertension

Patients with compensated cirrhosis are usually asymptomatic.[17] Initial symptoms may be nonspecific including fatigue, loss of appetite, and weight loss. Patients may also present with much more significant symptomatology secondary to decompensation related to cirrhosis complications such as ascites (abdominal distention) and HE (confusion, lethargy).

The approach to a patient with suspected liver disease begins with a thorough history and physical examination. In addition to fatigue, loss of appetite, and weight loss, patients may also experience other nonspecific signs. Muscle wasting, palmar erythema, spider nevi, parotid gland enlargement, white nails, Dupuytren contracture, asterixis and metabolic complications including gynecomastia, testicular atrophy, and axillary hair loss are all possibly related to cirrhosis.

Diagnostics for cirrhosis include liver function tests, coagulation tests, complete blood count, and serologic tests for viral causes including hepatitis B and C. A thorough history is key in determining if alcoholism is the likely cause of a patient's cirrhosis. A basic history and physical may also uncover the presence of obesity and history of diabetes that are suggestive of nonalcoholic fatty liver disease. Additional testing may include an antinuclear antibody titer to evaluate for the presence of autoimmune hepatitis; serum iron and transferrin saturation, possibly in conjunction with genetic testing, to look for hemochromatosis; and alpha-1 antitrypsin level and genotyping to test for alpha-1 antitripysin deficiency, a rare disease, but one that can lead to liver disease as well as lung damage. When the underlying cause is still unable to be elucidated, additional testing for antimitochondrial antibodies or a magnetic resonance cholangiopancreatography to look for strictures and dilations of the bile ducts indicating primary biliary cholangitis may be completed. Wilson disease can be screened for using serum ceruloplasmin and copper levels.

Liver Chemistries

Liver chemistries or liver tests are actually markers of liver injury rather than function, though they are commonly referred to as liver function tests.[19] A comprehensive metabolic profile includes AST, ALT, alkaline phosphatase, bilirubin, and albumin. Additionally, the PT and GGT are needed. Liver chemistries are part of the initial evaluation of a patient with symptoms or signs suggestive of cirrhosis.[18] The use of liver function tests in the diagnosis and management of cirrhosis is discussed in the following sections. It may be useful to group the tests into two broad categories: (1) markers of liver injury such as AST, ALT and alkaline phosphatase and (2) markers of hepatocellular function such as PT, bilirubin, and albumin.[19]

Aminotransferases

The aminotransferases, AST and ALT, are enzymes involved in the transfer of amino groups of aspartate and alanine to ketoglutaric acid. Also referred to as transaminases, their presence in serum is a marker of hepatocellular injury. While AST is present in the liver, cardiac tissue, skeletal muscle, kidney, and brain, ALT is primarily in the liver. Liver injury, whether acute or chronic, results in increases in the serum concentrations of the aminotransferase enzymes. The degree of elevation, rate of rise, and whether AST > ALT or ALT > AST are helpful in suggesting possible etiologies.

Transaminases will typically be severely elevated as a result of acute insults including conditions like acute viral hepatitis, autoimmune hepatitis, ischemic hepatitis/shock liver, acute Budd-Chiari syndrome, hepatic artery occlusion, diffuse infiltration of cancer into the liver, acute biliary obstruction, liver trauma, eclampsia, and Wilson disease. The highest elevations (>10,000 units per liter [167 μkat/L]) are most apt to occur in shock liver and drug- or toxin-induced hepatitis. Borderline and mild transaminase elevations are seen in a variety of liver and nonliver disease states.

The ratio of AST to ALT with AST>ALT is more likely when cirrhosis of any etiology exists but also occurs in alcoholic and ischemic liver disease. Seventy percent of patients with alcoholic liver disease had ratios greater than two and 92% of patients had ratios greater than one.[20]

Alkaline Phosphatase and γ-Glutamyl Transpeptidase

Elevated serum levels of alkaline phosphatase and GGT occur in cases of liver injury with a cholestatic pattern and therefore often accompany conditions such as primary biliary cirrhosis, primary sclerosing cholangitis, drug-induced cholestasis, and bile duct obstruction.[19] Alkaline phosphatase is not found solely in the liver. When elevations of alkaline phosphatase occur with subsequent elevations of transaminases, confirmation of hepatic origin is not needed. When alkaline phosphatase is elevated without other concurrent liver test abnormalities, the GGT is evaluated since combined elevations of both alkaline phosphatase and GGT levels increase clinical suspicion of hepatic etiology.

A mixed pattern liver injury is evidenced by elevations of both AST/ALT levels and alkaline phosphatase. An R ratio can be calculated in these cases which is achieved by utilization of the following formula: R = (ALT value/ALT upper limit of normal)/(alkaline phosphatase value/alkaline phosphatase upper limit of normal). An R ratio above 5 indicates hepatocellular injury. An R ratio below 2 indicates cholestatic disease. Ratios between 2 and 5 represent a mixed pattern.

Child-Pugh Classification and Model for End-Stage Liver Disease Score

The Child-Pugh classification system has gained widespread acceptance as a means of quantifying the myriad of effects of the cirrhotic process on the laboratory and clinical manifestations of this disease.[16] Recommended drug dosing adjustments for patients in liver failure are normally based on the Child-Pugh score. The newer MELD-Na scoring system is now the accepted classification scheme used by the Organ Procurement and Transplantation United Network for Organ Sharing (OPTN/UNOS) in the allocation livers for transplantation.[17] The Child-Pugh classification system employs a combination of physical and laboratory findings (Table 55-2), whereas the MELD score calculation takes into account a patient's serum creatinine, bilirubin, INR, and etiology of liver disease, omitting the more subjective reports of ascites and encephalopathy used in the Child-Pugh system.

TABLE 55-2

Criteria and Scoring for the Child-Pugh Grading of Chronic Liver Disease

Score	1	2	3
Total bilirubin (mg/dL)	<2 (34.2 µmol/L)	2-3 (34.2-51.3 µmol/L)	>3 (51.3 µmol/L)
Albumin (g/dL)	>3.5 (35 g/L)	2.8-3.5 (28-35 g/L)	<2.8 (28 g/L)
Ascites	None	Mild	Moderate
Encephalopathy (grade)	None	1 and 2	3 and 4
Prothrombin time (seconds prolonged)	<4	4-6	>6

Grade A,<7 points; grade B, 7-9 points; grade C, 10-15 points.

Data from Reference 16.

The MELD scoring calculation is as follows[21]:

$$\text{MELD score}^* = 9.57 \times \log_e(\text{creatinine [mg/dL]}) + 3.78 \times \log_e(\text{bilirubin [mg/dL]}) + 11.20 \times \log_e(\text{INR}) + 6.43$$

or using SI units:

$$\text{MELD score}^* = 9.57 \times \log_e(\text{creatinine [}\mu\text{mol/L]} \times 0.01131) + 3.78 \times \log_e(\text{bilirubin [}\mu\text{mol/L]} \times 0.05848) + 11.20 \times \log_e(\text{INR}) + 6.43$$

$$\text{MELD-Na score} = \text{MELD} - (\text{sodium [mEq/L]}) - (0.025 \times \text{MELD} \times (140 - \text{sodium [mEq/L]})) + 140$$

or using SI units:

$$\text{MELD-Na score} = \text{MELD} - (\text{sodium [mmol/L]}) - (0.025 \times \text{MELD} \times (140 - \text{sodium [mmol/L]})) + 140$$

These classification systems are important because they are used to assess and define the severity of cirrhosis, and predict patient survival, surgical outcome, and risk of variceal bleeding.

Bilirubin

Bilirubin is the product of the breakdown of hemoglobin molecules.[19] Elevations in serum conjugated (or direct) bilirubin indicate hepatocellular dysfunction or cholestasis. When total bilirubin elevation exists, it should be fractionated into direct (conjugated) and indirect (unconjugated) levels. Indirect bilirubin elevations occur due to over-production (as seen with hemolysis), decreased uptake, or decreased hepatic conjugation of bilirubin and can be found in conditions like Gilbert's syndrome. Direct hyperbilirubinemia is the result of liver injury or biliary obstruction and is associated with a number of hepatic diseases including cirrhosis. When cirrhosis has been established, the degree of bilirubin elevation has prognostic significance and is used as a component of the Child-Pugh and MELD scoring systems for quantifying the severity of cirrhosis.[16,21]

Albumin and Coagulation Factors

Albumin and coagulation proteins are markers of hepatic synthetic activity and are therefore used to estimate the level of hepatic functioning in cirrhosis. Albumin and PT are used in the Child-Pugh system for quantifying liver disease, and the INR is used in the MELD scoring system as a marker of coagulation.[16,21] Reduction in albumin usually indicates a disease duration of more than 3 weeks whereas severe liver disease can cause PT elevation in less than 24 hours. These tests are not specific to liver disease as any significant illness can reduce albumin levels and the PT can be elevated for a variety of reasons including anticoagulation with warfarin, vitamin K deficiency, and steatorrhea.

Thrombocytopenia

Thrombocytopenia is a common feature of chronic liver disease.[15] The platelet count is rarely below 30,000/mm^3 to 40,000/mm^3 (30 × 10^9/L to 40 × 10^9/L) though. When liver abnormality is suspected, a complete blood cell count that includes platelets should be evaluated.

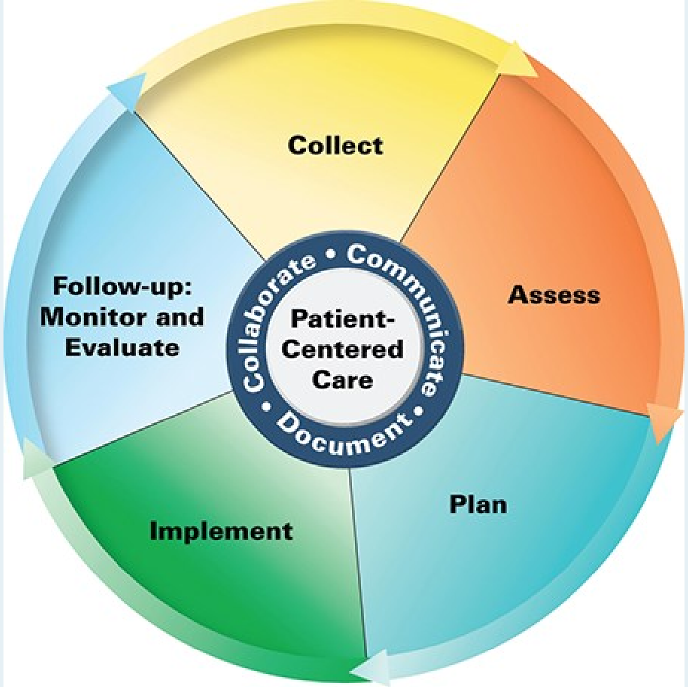
Imaging and Biopsy

Ultrasound technology can be used to detect more advanced cirrhosis as well as to evaluate the presence of portal hypertension and ascites. A liver in the stage of advanced cirrhosis will appear nodular on ultrasound.[18] Ultrasound may also be used to evaluate the presence of portal hypertension and ascites. Elastography via ultrasound or magnetic resonance may be useful in early cirrhosis or when other imaging is not definitive. Sometimes a liver biopsy is required when less invasive testing is inconclusive or when the results of biopsy may dictate the most appropriate management for the patient.

TREATMENT

Patient Care Process

Patient Care Process for Cirrhosis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient medical history
    - Recent history of anorexia or weight loss
    - Risk factors for hepatitis B and C
    - Personal and family history of autoimmune or hepatic diseases
- Social history (specifically ethanol use—quantity and duration)
- Current medications including nonprescription medications

- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Laboratory findings including albumin, bilirubin, complete blood count (CBC) with platelets, prothrombin time (PT), international normalized ratio (INR), alkaline phosphatase, aspartate transaminase (AST), alanine transaminase (ALT), gamma-glutamyl transpeptidase (GGT)

Assess

- Presence of jaundice, palmar erythema, and spider nevi
- Presence of medications that can cause cirrhosis (see Table 55-1)
- Presence of complications of cirrhosis (ascites, portal hypertension, esophageal varices, hepatic encephalopathy, coagulation disorders)
- Child-Pugh score (see Table 55-2) for need for medication dosage adjustments
- Patient's willingness to stop drinking alcohol

Plan*

- Identify and treat possible causes of cirrhosis (ie, hepatitis C)
- Remove offending medications that may cause or exacerbate cirrhosis or complications of cirrhosis
- Create a plan to treat acute complications of cirrhosis, if present
    - Ascites: sodium restriction and furosemide + spironolactone (see Table 55-3)
    - Portal hypertension

        Primary prevention of esophageal varices: beta-blocker (nadolol, propranolol, or carvedilol) and/or EVL for prevention

        Treatment of acute variceal bleeding: octreotide + EVL, SBP prophylaxis (eg, ceftriaxone) × 7 days (see Fig. 55-4 and Table 55-4)

        Secondary prevention: nadolol or propranolol + EVL
    - Spontaneous bacterial peritonitis

        Treatment: empiric antibiotic therapy with appropriate antibiotic (eg, cefotaxime) based on ascitic fluid PMN count and/or symptoms (see Table 55-3)

        Secondary prevention: ciprofloxacin daily (see Table 55-3)
    - Hepatic encephalopathy: dietary protein restriction and lactulose +/− rifaximin

Implement

- Provide patient education and assistance for achieving abstinence from alcohol, if applicable
- Discuss all elements of treatment plan (medications and dietary modifications) with patient
- Provide vaccines as indicated
- Adjust medication doses as needed based on major organ function and patient characteristics.
- Plan to assess progress of treatment including efficacy and adverse effects of treatments (see Table 55-5)

Follow-Up: Monitor and Evaluate

- Monitor for long-term efficacy and adverse effects
- Patient’s adherence to alcohol abstinence, prescribed medications, and dietary modifications
- Resolution of complications of cirrhosis
- Evaluate for possibility of liver transplant and need for dietitian (ie, sodium and protein restriction)

TABLE 55-3

Evidence-Based Table of Selected Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Recommendation	Grade
Ascites	
Paracentesis should be performed in patients with apparent new-onset ascites	IC
Sodium restriction of 2,000 mg/day should be instituted as well as oral diuretic therapy with spironolactone and furosemide	IIaA
Diuretic-sensitive patients should be treated with sodium restriction and diuretics rather than serial paracentesis	IIaC
Refractory ascites	
Serial therapeutic paracenteses may be performed	IC
Postparacentesis albumin infusion of 6-8 g/L of fluid removed can be considered if more than 5 L is removed during paracentesis	IIaA
Treatment of SBP	
If ascitic fluid PMN counts are >250 cells/mm^3 (0.25 × 10^9/L), empiric antibiotic therapy should be instituted (cefotaxime 2 g every 8 hours)	IA
If ascitic fluid PMN counts are <250 cells/mm^3 (0.25 × 10^9/L), but signs or symptoms of infection exist, empiric antibiotic therapy should be initiated while awaiting culture results	IB
If ascitic fluid polymorphonuclear leukocyte counts are >250 cells/mm^3 (0.25 × 10^9/L), clinical suspicion of SBP is present, and the patient has a serum creatinine >1 mg/dL (88 µmol/L), blood urea nitrogen >30 mg/dL (10.7 mmol/L), or total bilirubin over 4 mg/dL (68.4 µmol/L), 1.5 g/kg albumin should be infused within 6 hours of detection and 1 g/kg albumin infusion should also be given on day 3	IIaB
Prophylaxis against SBP	
Short-term antibiotic prophylaxis should be used for 7 days to prevent SBP in cirrhosis patients with GI hemorrhage	IA
Patients who survive an episode of SBP should receive long-term prophylaxis with ciprofloxacin	IA
Patients with low-protein ascites (<1.5 g/dL [15 g/L]) plus at least one of the following: serum creatinine ≥1.2 mg/dL (106 µmol/L), blood urea nitrogen ≥25 mg/dL (8.9 mmol/L), serum sodium ≤ 130 mEq/L (mmol/L), or Child-Pugh score of ≥9 with bilirubin ≥3 mg/dL (51.3 µmol/L) may also justifiably receive long-term ciprofloxacin as prophylaxis	IA

Recommendation grading: Class I—Conditions for which there is evidence and/or general agreement; Class II—Conditions for which there is conflicting evidence and/or a divergence of opinion; Class IIa—Weight of evidence/opinion is in favor of efficacy; Class IIb—Efficacy less well established; Class III—Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful; Level A—Data from multiple randomized trials or meta-analyses; Level B—Data derived from single randomized trial or nonrandomized studies; Level C—Only consensus opinion, case studies, or standard of care.

Data from Reference 22.

TABLE 55-4

Evidence-Based Table of Selected Treatment Recommendations: Variceal Bleeding in Portal Hypertension

Recommendation	Grade
Prevention of variceal bleeding	
Nonselective β-blocker therapy should be initiated in:	
Patients with small varices and criteria for increased risk of hemorrhage	1b
Patients with medium/large varices	1a
EVL may be recommended for prevention in patients with medium/large varices at high risk of hemorrhage instead of nonselective β-blocker therapy	1a
Treatment of variceal bleeding	
Short-term antibiotic prophylaxis should be instituted on admission	1a
Vasoactive drugs should be started as soon as possible, prior to endoscopy, and maintained for up to 5 days	1a
Endoscopy should be performed to diagnose variceal bleeding and treat bleeding with EVL	1b
Endoscopy should be performed within 12 hours of presentation	5
Unless contraindicated, erythromycin 250 mg IV should be administered 30-120 minutes prior to endoscopy	1b
Secondary prophylaxis of variceal bleeding	
Nonselective β-blocker therapy plus EVL is the best therapeutic option for prevention of recurrent variceal bleeding	1a

Recommendation grading:

1a Systematic review (with homogeneity) of randomized controlled trials

1b Individual randomized controlled trial with narrow confidence interval

1c All or none

2a Systematic review (with homogeneity) of cohort studies

2b Individual cohort study (including low-quality randomized controlled trial)

2c Outcomes research; ecological studies

3a Systematic review (with homogeneity) of case-controlled studies

3b Individual case-control study

4 Case-series (and poor quality cohort and case-control studies)

5 Expert opinion

Data from Reference 12.

TABLE 55-5

Drug Monitoring Guidelines

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Nonselective β-adrenergic blocker	Heart failure, bronchospasm, glucose intolerance	BP, HR Goal BP: Sytolic >90 mm Hg Goal HR: 55-60 beats/min or maximal tolerated dose	Nadolol, propranolol
Nonselective β-adrenergic blocker; alpha-blocker	Similar to nonselective β-adrenergic blocker, but potentially better tolerated	Goal BP: Sytolic > 90 mm Hg	Carvedilol
Octreotide	Bradycardia, hypertension, arrhythmia, abdominal pain	BP, HR, EKG, abdominal pain	
Spironolactone/furosemide	Electrolyte disturbances, dehydration, renal insufficiency, hypotension	Serum electrolytes (especially potassium), SCr, blood urea nitrogen, BP Goal sodium excretion: >78 mmol/day	Spot urine sodium concentration greater than potassium concentration correlates well with daily sodium excretion >78 mmol/day
Lactulose	Electrolyte disturbances	Serum electrolytes Goal number of soft stools per day: 2-3	
Neomycin	Ototoxicity, nephrotoxicity	SCr, annual auditory monitoring	
Metronidazole	Neurotoxicity	Sensory and motor neuropathy	
Rifaximin	Nausea, diarrhea		

BP, blood pressure; HR, heart rate; beats/min, beats per minute; EKG, electrocardiogram; SCr, serum creatinine; mmol, millimole.

General Approaches to Treatment

General approaches to therapy in cirrhosis should include the following:

1. Identify and eliminate, where possible, the causes of cirrhosis (eg, alcohol misuse).
2. Assess the risk for variceal bleeding and begin pharmacologic prophylaxis when indicated. Prophylactic endoscopic therapy can be used for patients with high-risk medium and large varices as well as in patients with contraindications or intolerance to nonselective β-adrenergic blockers. Endoscopic therapy is also appropriate for patients suffering acute bleeding episodes. Variceal obliteration with endoscopic techniques in conjunction with pharmacologic intervention is the recommended treatment of choice in patients with acute bleeding.
3. Evaluate the patient for clinical signs of ascites and manage with pharmacologic therapy (eg, diuretics) and paracentesis. Careful monitoring for SBP should be used in patients with ascites who experience acute deterioration of their clinical status.
4. Recognize that HE is a common complication of cirrhosis that requires clinical vigilance and treatment with dietary restriction, elimination of precipitating factors, and therapy to lower ammonia levels.
5. Monitor patients for signs of hepatorenal syndrome, pulmonary insufficiency, and endocrine dysfunction.

Desired Outcomes

Portal hypertension and cirrhosis can be classified as compensated versus decompensated.[23] In compensated portal hypertension, though HVPG may be elevated and varices may be present, the patient does not experience complications of cirrhosis such as variceal bleeding, ascites, SBP, or encephalopathy. The desired therapeutic outcomes during the compensated stage include *prevention of complications* through therapeutic modalities such as lowering of portal pressure with medical therapy using nonselective β-adrenergic blocker therapy and supporting abstinence from alcohol. In patients with decompensated cirrhosis, *resolution of acute complications* becomes the desired therapeutic outcome. Treatment modalities and therapeutic goals are presented below for each of the primary complications of decompensated portal hypertension. Recommended therapies and therapeutic goals are discussed.

Management of Portal Hypertension and Variceal Bleeding

The management of varices involves three strategies: (a) primary prophylaxis (prevention of the first bleeding episode), (b) treatment of acute variceal hemorrhage, and (c) secondary prophylaxis (prevention of rebleeding in patients who have previously bled).[11] It is also possible for a patient to have been diagnosed with cirrhosis and portal hypertension but have no varices. These patients would be considered to be in a preprimary prophylaxis stage. No specific treatment is recommended for preprimary prophylaxis and, for that reason, the focus of this chapter will be primary prophylaxis, treatment of acute variceal bleeding, and secondary prophylaxis.

Primary Prophylaxis

β-Adrenergic Blockade

The mainstay of primary prophylaxis is the use of nonselective β-adrenergic blocking agents such as propranolol, nadolol, or carvedilol.[11,12,23] These agents reduce portal pressure by reducing portal venous inflow via two mechanisms: a decrease in cardiac output through β_1-adrenergic blockade and a decrease in splanchnic blood flow through β_2-adrenergic blockade that results in unopposed α-1 activity.[11]

Endoscopic Variceal Ligation (EVL)

Endoscopic variceal ligation is an endoscopic therapy that consists of placing rubber bands around varices until the varices are obliterated.

Treatment Recommendations: Variceal Bleeding—Primary Prophylaxis

② All patients with cirrhosis should be screened for varices at the time of diagnosis.[11,12] Transient elastography that shows liver stiffness below 20 kPa in patients with platelets over 150,000/mm^3 (150 × 10^9/L) do not require screening endoscopy.[12,23] Others should undergo screening endoscopy to identify and evaluate varices. β-Adrenergic blocker therapy is not indicated in patients without varices to prevent the formation of varices.[11,12,23] Patients with small varices plus risk factors for variceal hemorrhage including red wale marks or Child-Pugh grade C should receive prophylactic therapy with a nonselective β-adrenergic blocker. β-Adrenergic blocker therapy is recommended preferentially to EVL in this situation due to the technical difficulty of EVL in the treatment of small varices. β-Adrenergic blocker therapy is optional for patients with small varices in the absence of risk factors, but additional studies to confirm benefit in this population are needed. All patients found to have medium to large varices that have not bled should receive primary prophylaxis therapy with a nonselective β-adrenergic blocker or EVL. The choice of treatment should be based on a consideration of resources and expertise as well as patient preferences and characteristics with a particular emphasis on side effects and contraindications.[12] If β-adrenergic blocker therapy is chosen, initiate therapy with oral propranolol 20 to 40 mg twice daily or nadolol 20 to 40 mg once daily and titrate every 2 to 3 days to a resting heart rate of 55 to 60 beats/min.[23] The daily dose of propranolol should not exceed 320 mg for patients without ascites or 160 mg for patients with ascites. The maximum daily dose of nadolol should not exceed 160 mg for patients without ascites or 80 mg for those with ascites. Systolic blood pressure should be maintained above 90 mm Hg. Rather than propranolol or nadolol, carvedilol could be chosen and started at 3.125 mg twice daily with titration to 6.25 mg twice daily after 3 days. In addition to β-adrenergic blockade, carvedilol also provides anti-α-adrenergic activity and enhances the release of nitric oxide.[24,25] Carvedilol may be considered in patients unable to tolerate propranolol or nadolol due to side effects like fatigue, weakness, and shortness of breath as it is perceived to be better tolerated than the pure nonselective β-adrenergic blockers.[23] Unlike propranolol and nadolol, titration of carvedilol is not guided by resting heart rate measurement, though systolic blood pressure should be maintained above 90 mm Hg while on carvedilol as well. β-adrenergic blocker therapy should generally be continued indefinitely, but the patient must be monitored for development of contraindications such as renal impairment and hypotension that may accompany end-stage liver disease.[12] Following initiation and appropriate titration of the β-adrenergic blocker, further endoscopic surveillance is not needed.[11,23] If EVL is chosen, it will be performed every 2 to 8 weeks until the obliteration of varices.[23] Follow-up surveillance will occur at 3 to 6 months and again every 6 to 12 months thereafter.

Fifteen percent of patients have absolute contraindications to nonselective β-adrenergic blockers (ie, those with asthma or those with hypoglycemia unawareness while receiving antihyperglycemic therapy) and another 15% have common side effects such as fatigue, weakness, and shortness of breath that contribute to medication nonadherence.[11] Patients who qualify for β-adrenergic blocker therapy as primary prophylaxis, but who are unable to take or continue it, should be considered for alternative therapy with EVL.[12,23] Also, EVL may be considered as a possible first option for primary prophylaxis in patients with high-risk medium to large varices.

Acute Variceal Hemorrhage

Variceal hemorrhage is a medical emergency that carries a mortality rate of 7% to 15%, requires admission to an intensive care unit, and is one of the most feared complications of cirrhosis.[11] Treatment of acute variceal bleeding includes general stabilizing and assessment measures as well as specific measures to control the acute hemorrhage and prevent complications.

Initial treatment goals include (a) adequate blood volume resuscitation, (b) protection of airway from aspiration of blood, (c) prophylaxis against SBP and other infections, (d) control of bleeding, (e) prevention of re-bleeding, (f) preservation of liver function/prevention of HE, and (g) prevention of acute kidney injury.[25] Prompt stabilization of blood volume, with administration of packed red blood cells at a hemoglobin threshold of 7 g/dL (70 g/L; 4.34 mmol/L) and a goal hemoglobin of 7 g/dL (70 g/L; 4.34 mmol/L) to 9 g/dL (90 g/L; 5.59 mmol/L), should be undertaken.[22] Use of recombinant factor VIIa therapy is not recommended in patients with cirrhosis with GI hemorrhage.[11,23] Combination pharmacologic therapy plus endoscopic therapy with EVL (preferred), or sclerotherapy if EVL is not technically feasible, is considered the most rational approach to the treatment of acute variceal bleeding.[11,23,25] Endoscopy should be performed as soon as possible, but at least within 12 hours of admission.

Vasoactive drug therapy is used to stop or slow bleeding as soon as a diagnosis of variceal bleeding is suspected and is started before endoscopy.[11,23] The vasoactive drug used to manage acute variceal bleeding in the United States is the somatostatin analogue octreotide. Antibiotic therapy to prevent SBP and other infections should be implemented upon admission.[12] Intravenous ceftriaxone 1 g/24 hours is recommended.[12,23] A 250 mg dose of intravenous erythromycin prior to endoscopy may be used to accelerate gastric emptying of clots and improve visibility during the endoscopic procedure.[12,25] Should episodic HE occur secondary to acute GI bleeding, lactulose may be utilized. Figure 55-4 presents an algorithm for the management of variceal hemorrhage.

Octreotide

The splanchnic vasoconstriction from octreotide therapy is due to inhibition of the release of vasodilatory peptides such as glucagon; however, a local vasoconstrictive effect also exists.[26] Somatostatin analogues, including octreotide, are associated with fewer side effects as compared with the most potent splanchnic vasoconstrictor, vasopressin. The primary side effects of octreotide therapy are hyperglycemia, vomiting, bradycardia, hypertension, arrhythmia, and abdominal pain.[11,25] The recommended dosing of octreotide for variceal bleeding consists of an initial IV bolus of 50 μg followed by a continuous IV infusion of 50 μg/h.[11,23] Octreotide can be continued for 2 to 5 days after acute variceal bleeding in an effort to prevent re-bleeding. Vasoactive therapy discontinuation can be considered once the patient is free of bleeding for at least 24 hours.

Prevention of Spontaneous Bacterial Peritonitis

Patients with cirrhosis with active bleeding are at high risk of severe bacterial infections.[23] Short-term prophylactic antibiotic therapy to reduce the risk of infection during episodes of bleeding not only reduces the likelihood of infections but also reduces the incidence of rebleeding and increases survival.[27] For these reasons, a short course (7 days maximum) of IV ceftriaxone 1 g daily is recommended.[12,27,28] Oral norfloxacin was once recommended as an alternative to IV ceftriaxone in cases where the patient had not been previously receiving quinolone therapy and when the prevalence of quinolone-resistant bacteria was low, but norfloxacin is no longer available.[23] Oral ciprofloxacin could be considereded instead, but ceftriaxone is typically used today and is preferred in patients with advanced cirrhosis, in areas of high quinolone resistance, and in patients who have received quinolone therapy for ongoing SBP prophylaxis.

Endoscopic Interventions: Sclerotherapy and Band Ligation

Guidelines recommend that endoscopy be performed within 12 hours of admission in cases of upper GI bleeding.[12,23] Endoscopy is used to diagnose variceal bleeding, and endoscopic techniques, particularly EVL, are used to stop variceal bleeding. EVL can be repeated if hemorrhage is not controlled or in the event of early recurrence of bleeding (within the first 5 days).[12] EVL is more effective than sclerotherapy with greater control of hemorrhage, less risk for rebleeding, lower likelihood of adverse events, and lower mortality.[11] Consensus recommendation calls for EVL (in conjunction with pharmacologic therapy) as the recommended form of endoscopic therapy for acute variceal bleeding.[12] Endoscopic injection of the tissue adhesive *N*-butyl cyanoacrylate is recommended to control acute *gastric* variceal bleeding from isolated gastric varices and gastroesophageal varices type 2 that extend beyond the cardia. EVL or tissue adhesive can be used for bleeding from gastroesophageal varices type 1. A pre-endoscopy infusion of erythromycin 250 mg IV, 30 to 120 minutes prior to the procedure, is recommended in the absence of QT interval prolongation.

Interventional and Surgical Treatment Approaches

Child-Pugh Class C patients and those in Class B with active hemorrhage at the time of diagnostic endoscopy make up less than 20% of patients admitted with variceal hemorrhage, but these patients do comprise a group who are at high risk for failing standard therapy with EVL plus octreotide.[11] In these cases, early transjugular intrahepatic portosystemic shunt (TIPS) may be considered instead of standard therapy.[23] The TIPS procedure involves the placement of one or more stents between the hepatic vein and the portal vein (Fig. 55-5). TIPS (preferably with polytetrafluoroethylene-covered stents) is also recommended for patients who fail to achieve or maintain hemostasis despite combined endoscopic and pharmacologic therapy.[23]

FIGURE 55-5

Transjugular intrahepatic portosystemic shunt.

Balloon tamponade may be used as a bridge therapy to control variceal bleeding temporarily (maximum of 24 hours).[12,23] It should be reserved as a temporizing measure until a more definitive treatment, such as TIPS, can be performed.

Treatment Recommendations: Variceal Hemorrhage

④ Patients require cautious resuscitation with blood products to correct intravascular losses.[23] Drug therapy with octreotide should be initiated early to control bleeding and facilitate diagnostic and therapeutic endoscopy. Therapy is initiated with an IV bolus of 50 μg and is followed by a continuous infusion of 50 μg/hr for 2 to 5 days.[11,23] Patients should be monitored for bradycardia, hypertension, arrhythmia, and abdominal pain.[11,25] Endoscopy is recommended in any patient with suspected upper GI bleeding due to ruptured varices.[12,23] EVL is the recommended form of endoscopic therapy. An additional endoscopic therapy option is injection of the tissue adhesive *N*-butyl cyanoacrylate for gastric varices.[12] Short-term antibiotic prophylaxis (maximum 7 days) is recommended.[12,23] Ceftriaxone 1 g IV daily is the preferred antibiotic selection for this indication.[23] Surgical procedures like TIPS are employed as salvage therapy in patients who have failed repeated endoscopy and vasoactive drug therapy.[12,23] In patients at highest risk for standard treatment failure, a preemptive decision to utilize early TIPS may occur.

Secondary Prophylaxis

Because rebleeding after initial control of variceal hemorrhage occurs in a median of 60% of patients, and because rebleedingg carries a mortality rate of 33%, it is inappropriate to simply observe patients for evidence of further bleeding.[11,23] Only patients who undergo shunt surgery or TIPS to control their initial acute bleeding require no further intervention as secondary prophylaxis. Patients who undergo one of these procedures to treat their initial bleeding should be referred for transplantation if they are a candidate. For all others, combination therapy with a β-adrenergic blocker and chronic EVL to eradicate varices is the treatment of choice for secondary prophylaxis of variceal bleeding.[11,12,23] Nadolol and propranolol are the recommended β-adrenergic blockers for secondary prophylaxis because carvedilol has not been studied adequately for the prevention of rebleeding.[12,23] Secondary prophylaxis should be started once vasoactive drug therapy is discontinued and as soon as possible (as early as day 6) following the acute bleeding event.[11]

Treatment Recommendations: Variceal Bleeding—Secondary Prophylaxis

③ The combination of EVL and a nonselective β-adrenergic blocking agent is recommended since pharmacologic therapy provides protection against rebleeding until EVL can be repeated a sufficient number of times to obliterate all varices.[11,23] Pharmacologic therapy should be initiated with a nonselective β-adrenergic blocker such as propranolol 20 to 40 mg twice daily or nadolol at a dose of 20 to 40 mg once daily.[23] β-Adrenergic blocker therapy is titrated every 2 to 3 days to achieve a goal heart rate of 55 to 60 beats/min maintaining systolic blood pressure above 90 mm Hg. Maximum doses of propranolol 320 mg/day for patients without ascites and 160 mg/day for patients with ascites, and nadolol 160 mg/day for patients without ascites and 80 mg/day for patients with ascites are recommended. Patients should also be monitored for evidence of bradycardia, bronchospasm, and hypoglycemia, particularly in patients with insulin-dependent diabetes, as well as symptoms of heart failure and excessive sodium and water retention.[11,24] EVL should be conducted every 1 to 4 weeks until variceal obliteration, then the patient should be followed by surveillance endoscopy in 3 to 6 months and every 6 to 12 months thereafter.[23]

The addition of isosorbide mononitrate to nonselective β-adrenergic blocker therapy reduces portal pressure more than a β-adrenergic blocker alone, but there is no difference in the overall rate of rebleeding with this combination and side effects are more likely than with β-adrenergic blocker monotherapy (namely, headache and light-headedness).[23] Pharmacologic therapy (either isosorbide mononitrate plus nonselective β-adrenergic blocker therapy or β-adrenergic blocker therapy alone) plus EVL is associated with lower rebleeding rates than EVL therapy alone, but is only moderately more effective than isosorbide mononitrate plus nonselective β-adrenergic blocker therapy.[29] Thus, drug therapy is considered the cornerstone for secondary prophylaxis against variceal bleeding and patients who cannot tolerate nonselective β-adrenergic blocker therapy should be considered for TIPS.[23]

The lowest rate of variceal rebleeding occurs in patients when pharmacologic therapy leads to a reduction in HVPG of greater than 20% of baseline or to a measurement less than 12 mm Hg (1.6 kPa).[23] Ideally, portal pressure monitoring would be used to assess the response to nonselective β-adrenergic blocker therapy and identify responders from nonresponders earlier in the treatment course.

There is ongoing debate regarding the use of β-adrenergic blockers for prophylaxis against variceal bleeding in patients with refractory ascites.[24] The Baveno VI Consensus statement recommends reduction or temporary discontinuation of β-adrenergic blockers in patients receiving secondary prophylaxis with systolic blood pressure <90 mm Hg, serum sodium <130 mEq/L (mmol/L), or acute kidney injury.[12] This recommendation assumes that other precipitating drug therapies have already been removed. Reinitiation of β-adrenergic blocker therapy can be considered if the patient's circulatory dysfunction improves. A summary of evidence-based treatment recommendations regarding portal hypertension and variceal bleeding is presented in Table 54-3.[10,11,21]

Management of Ascites and Spontaneous Bacterial Peritonitis

Ascites is the most common first sign of decompensation in patients with cirrhosis and represents a clinically important milestone in the natural progression of the disease.[10] The classic physical examination findings of ascites are a bulging abdomen with shifting flank dullness.[9,22] The development of ascites in patients with cirrhosis is an indication of advanced liver disease and is a poor prognostic sign.[10] Workup includes a history and physical examination, abdominal paracentesis and/or ultrasound, and ascitic fluid analysis.[9,22]

Spontaneous bacterial peritonitis is an infection of ascitic fluid that occurs in the absence of any evidence of an intraabdominal, surgically treatable source of infection. It is a common complication that develops in 1.5% to 3.5% of outpatients with cirrhosis and 10% of inpatients with cirrhosis.[9] The altered intestinal permeability and resultant bacterial translocation, in addition to changes in intestinal microbiota and immune system dysfunction place these patients at risk for developing SBP.[30] Most episodes of SBP have traditionally been caused by *Escherichia coli, Klebsiella pneumonia*, and pneumococci.[22] Concerns over quinolone-resistant bacteria and multidrug-resistant organisms have been recognized in clinical guidelines.[31] Symptoms and signs of SBP include abdominal pain, diarrhea, vomiting, and nonspecific symptoms, and patients may be asymptomatic.[32] Diagnostic paracentesis with analysis of ascitic fluid should be performed in all patients newly diagnosed with ascites.[9,22] SBP is diagnosed when there is positive ascitic fluid bacterial culture and ascitic fluid cell counts show an absolute polymorphonuclear (PMN) leukocyte count of greater than or equal to 250 cells/mm^3 (0.25 × 10^9/L).

Treatment guidelines for the management of adult patients with ascites and SBP were updated and approved by the Practice Guidelines Committee of the American Association for the Study of Liver Diseases (AASLD) in 2012.[22] The European Association of the Student of the Liver (EASL) published ascites guidelines in 2018. A synopsis of these guidelines follows.[31]

Ascites

In adult patients with new-onset ascites as determined by physical examination or radiographic studies, abdominal paracentesis should be performed, and ascitic fluid analysis should include a cell count with differential, ascitic fluid total protein, and a serum-ascites albumin gradient (SAAG).[22] If infection is suspected, ascitic fluid cultures should be obtained at the time of the paracentesis. The SAAG can accurately determine whether ascites is a result of portal hypertension or another process. If the SAAG is greater than or equal to 1.1 g/dL (11 g/L), the patient almost certainly has portal hypertension. The treatment of ascites secondary to portal hypertension is relatively straightforward and includes abstinence from alcohol, sodium restriction, and diuretics.

① Abstinence from alcohol is an essential element of the overall treatment strategy. Abstinence from alcohol can result in improvement of the reversible component of alcoholic liver disease, resolution of ascites, or improved responsiveness of ascites to medical therapy. Patients with cirrhosis not caused by alcohol have less reversible liver disease, and, by the time ascites is present, these patients may be best managed with liver transplantation rather than protracted medical therapy.

Beyond avoidance of alcohol, the primary treatment of ascites due to portal hypertension and cirrhosis is sodium restriction to 2,000 mg/day and oral diuretic therapy. Fluid loss and weight change depend directly on sodium balance in these patients. A goal of therapy is to increase urinary excretion of sodium to greater than 78 mmol/day. Evaluation of urinary sodium excretion, preferably utilizing a 24-hour urine collection, may be helpful, although this collection can be difficult. A random spot urine sodium concentration that is greater than the potassium concentration correlates well with a 24-hour urinary sodium excretion over 78 mmol/day and is an easier test to complete. Severe hyponatremia, defined as serum sodium less than a threshold of 120 mEq/L (mmol/L), does warrant fluid restriction. However, hyponatremia of this severity is rare among patients with cirrhosis and ascites and, for this reason, rarely requires specific treatment.

Diuretic Therapy

⑤ The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spironolactone 100 mg and furosemide 40 mg by mouth daily in the morning, titrated every 3 to 5 days utilizing a ratio of 100:40 to attain adequate natriuresis and weight loss (reasonable daily weight loss goal is 0.5 kg). Maximum daily doses are 400 mg spironolactone and 160 mg furosemide. The EASL guidelines recommend initiation of diuretic therapy with spironolactone alone for the first occurrence of ascites with titration every 3 days to a maximum of 400 mg daily.[31] Subsequent addition of furosemide is recommended by the EASL in those with insufficient weight loss, hyperkalemia, or longstanding or recurring ascites. Due to the likelihood for development of drug-induced hyperkalemia with spironolactone when used as monotherapy at doses sufficient to illicit a sufficient diuresis, combination therapy is most typically employed in this country, except in patients with minimal fluid overload.[29] Furosemide as lone diuretic therapy is inferior to spironolactone in the treatment of ascites and is not recommended. Serum potassium and renal function should be monitored frequently and rapid correction of asymptomatic hyponatremia in patients with cirrhosis should be avoided. Diuretic therapy should be discontinued in patients who experience uncontrolled or recurrent encephalopathy, severe hyponatremia (serum sodium <120 mEq/L [mmol/L]) despite fluid restriction, or renal insufficiency (serum creatinine >2 mg/dL [177 μmol/L]).

If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. In patients with refractory ascites, serial paracenteses may be employed. Albumin infusion of 6 to 8 g/L of fluid removed can be considered post-paracentesis is reasonable for extraction volumes exceeding 5 L. Referral for liver transplantation should be made in patients with refractory ascites. TIPS is a therapeutic modality for the treatment of refractory ascites that may be considered in appropriately selected patients. Peritoneovenous shunting may be considered in treatment-refractory patients who are not candidates for paracenteses, transplant, or TIPS.

Patients with cirrhosis and ascites should avoid nonsteroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, and angiotensin receptor blockers except under special circumstances. Angiotensin converting enzyme inhibitors and angiotensin receptor blockers should not be used in patients with refractory ascites. While these therapies are not part of the standard therapies of the complications of cirrhosis, nonselective β-adrenergic blocker therapy is indicated for primary and secondary prophylaxis against variceal bleeding in portal hypertension. Unfortunately, nonselective β-adrenergic blocker therapy can cause hypotension in patients with refractory ascites making the condition worse. For this reason, the risks versus benefits of nonselective β-adrenergic blocker therapy in refractory ascites must be carefully weighed, and nonselective β-adrenergic blockers avoided or not started in this population unless the benefit of bleeding prophylaxis outweighs the risk of worsening ascites. The daily dose of propranolol should not exceed 160 mg for patients with ascites.[22] The maximum daily dose of nadolol should not exceed 80 mg for those with ascites. Systolic blood pressure should be maintained above 90 mmHg.

Spontaneous Bacterial Peritonitis

Relatively broad-spectrum antibiotic therapy that adequately covers the most commonly encountered pathogens (*E. coli, K. pneumoniae*, and pneumococci) has been recommended in patients with documented or suspected SBP.[22] Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm^3 (0.25 × 10^9/L) should receive empiric antibiotic therapy.[22,31] The AASLD guidelines specify IV cefotaxime 2 g every 8 hours or a similar third-generation cephalosporin.[22] The EASL guidelines recommend a third-generation cephalosporin (eg, cefotaxime or ceftriaxone) or piperacillin/tazobactam when SBP is community-acquired (ie, when diagnosed at time of admission or within 48 hours of admission).[30,31] Piperacillin/tazobactam is recommended in areas of low MDRO rates for patients without sepsis who are diagnosed within 90 days of previous contact with a hospital system or who live in a residential healthcare facility. In areas of high MDRO rates, or in cases of nosocomial-associated SBP (ie, SBP diagnosed after 48 hours of hospitalization or earlier in a patient who spent at least 48 hours admitted within the past 90 days), carbapenems alone or in combination with daptomycin, vancomycin, or linezolid are recommended. Patients with SBP who previously received quinolone therapy as prophylaxis should be treated with an alternative agent because patients who have received quinolone therapy may become infected with quinolone-resistant flora.[22]

Empiric therapy should not be delayed while awaiting culture results. In some patients, signs and symptoms of infection are present such as fever, abdominal pain, and unexplained encephalopathy at the bacterascites stage (ie, signs and symptoms are present before the PMN count in the ascitic fluid is elevated). In these patients, signs and symptoms of infection justify empiric antibiotic therapy until culture results are known, regardless of the PMN count in the ascitic fluid. An antibiotic course of 5 to 7 days is currently recommended for the treatment of SBP.[30,31]

AASLD and EASL also recommend albumin infusion in patients with SBP who, in addition to PMN counts of 250 cells/mm^3 (0.25 × 10^9/L) or greater, also have at least one of the following: SCr over 1 mg/dL (88 µmol/L), BUN over 30 mg/dL (10.7 mmol/L), or total bilirubin over 4 mg/dL (68.4 µmol/L).[22,31] Albumin IV 1.5 g/kg body weight within 6 hours of SBP detection followed by 1 g/kg on day 3 (maximum dose 100 g) is recommended. This is then followed by an additional albumin IV infusion of 1 g/kg on day 3 (maximum dose 100 g). ⑥ All patients who have survived an episode of SBP should receive long-term antibiotic prophylaxis with daily ciprofloxacin 500 mg daily (since norfloxacin is no longer available).[22,28,31] Long-term prophylaxis should also be considered for the prevention of SBP in patients with low-protein ascites (<1.5 g/dL [15 g/L]) who also have one of the following: serum creatinine greater than or equal to 1.2 mg/dL (106 µmol/L), blood urea nitrogen greater than or equal to 25 mg/dL (8.9 mmol/L), serum sodium less than or equal to 130 mEq/L (mmol/L), or Child-Pugh score of greater than or equal to 9 with bilirubin greater than or equal to 3 mg/dL (51.3 µmol/L).[22,31] Short-term prophylaxis (7 days) is indicated in patients with cirrhosis and GI hemorrhage.[12,23] Rifaximin, a synthetic antibiotic which is not systemically absorbed and acts locally within the gastrointestinal tract, is superior to no antibiotic therapy for primary and secondary prophylaxis against SBP.[33] However, it remains undetermined if rifaximin is superior to systemically absorbed antibiotics for SBP prophylaxis. A summary of evidence-based treatment recommendations regarding ascites and SBP is given in Table 55-3.

Management of Hepatic Encephalopathy

Hepatic encephalopathy will occur in 30% to 40% of patients with cirrhosis at some point during the course of their disease.[13] The clinical manifestations of HE vary widely from subclinical alterations to coma. In addition to classification based on underlying disease, HE is also classified based on severity, time course, and the presence of precipitating factors. To determine the severity of HE, a grading system that relates neurologic and neuromuscular signs can be used (Table 55-6). The time course of HE is classified as episodic, persistent, or recurrent. Recurrent HE refers to HE episodes that occur in time intervals less than 6 months apart. Persistent HE refers to behavioral symptoms that are always present and periodically interspersed with episodes of overt HE relapses. A precipitating factor or factors such as constipation, infection, diuretic overuse, GI bleeding, or electrolyte abnormalities can be identified in most episodic cases of HE related to cirrhosis, but spontaneous episodic HE can occur as well. The general approach to the management of HE is four pronged and includes the following: care for patients with altered consciousness, identify and treat any other causes besides HE for altered mental status, identify and treat any precipitating factors, and begin empiric HE treatment. Treatment for HE is primarily focused on reducing ammonia blood concentrations through drug therapy aimed at inhibiting ammonia production or enhancing its removal. Treatment for HE should include avoidance and prevention of precipitating factors in an effort to avoid acute decompensation. In cases where a precipitant of episodic HE has been identified and adequately treated or removed, long-term prophylaxis against another acute HE episode may not be required. Otherwise, chronic therapy to prevent acute decompensation is often required.

TABLE 55-6

Grading System for Hepatic Encephalopathy

Grade	Level of Consciousness	Personality/Intellect	Neurologic Abnormalities
Unimpaired	Normal	Normal	Normal
Minimal	No clinical evidence of change	No clinical evidence of change/alterations identified on psychometric or neuropsychological testing	No clinical evidence of change
I	Trivial lack of awareness; shortened attention span	Euphoria or anxiety; impairment of addition or subtraction	Altered sleep rhythm
II	Lethargic	Obvious personality changes; inappropriate behavior; apathy	Asterixis; dyspraxia; disoriented for time
III	Somnolent but arousable	Bizarre behavior	Responsive to stimuli; confused; gross disorientation to time and space
IV	Coma/unarousable	None	Does not respond to stimuli

Data from Reference 13.

Hyperammonemia

7 Treatment interventions to reduce ammonia blood concentrations are recommended in patients with HE. Decreasing ammonia blood concentrations by reducing the nitrogenous load from the gut remains a mainstay of therapy for patients with HE. Treatment options most commonly used to decrease ammonia load from the gut include nutritional management, nonabsorbable disaccharides, and antibiotics.

Guidelines for nutritional support of patients with liver disease have been published by the International Society for Hepatic Encephalopathy and Nitrogen Metabolism.[34] Protein withdrawal is a cornerstone of treatment for patients during acute episodes of HE.[13] However, prolonged restriction can lead to malnutrition and poorer prognosis among HE patients. Once successful reversal of HE symptoms is achieved, protein is added back to the diet in combination with other therapies until a target of 1.2 to 1.5 g/kg/day of protein is reached. Vegetable-source and dairy-source protein may be preferable to meat-source protein because the latter contains a higher calorie-to-nitrogen ratio. Also, the higher fiber content of vegetable protein lowers colonic pH, increasing catharsis. Oral branched-chain amino acid formulations improve symptoms in episodic HE and may be considered as alternative or add-on therapy in patients who do not respond to conventional measures.

The use of lactulose, a nonabsorbable disaccharide, is the standard therapy for both acute and chronic HE. Lactulose removes nitrogenous waste from the gastrointestinal tract through its laxative effect.[35] In addition, when it reaches the colon, it is metabolized by the microbiota in the lower gastrointestinal tract producing short-chain organic acids. These acids inhibit the growth of ammonia-producing bacteria further reducing the overall ammonia load in the gut. Another laxative, polyethylene glycol 3350, has been compared with lactulose for the treatment of acute HE.[36] Patients receiving polyethylene glycol 3350 had higher rates of HE symptom improvement after 24 hours and their acute HE resolved 1 day sooner than those who received lactulose. Polyethylene glycol may be considered for patients suffering an acute HE episode.

Neomycin has activity against most gram-negative bacteria and inhibits intestinal glutaminase thereby reducing bacterial production of glutamate and ammonia.[37] For this reason, oral neomycin can be used for the treatment of HE. However, this agent is rarely used due to the severity of its potential adverse effects including ototoxicity and nephrotoxicity. Anaerobic bacteria produce urease that hydrolyzes urea to ammonia in the gut. Metronidazole targets these gram-negative anaerobic gut bacteria and, as a result, can be utilized in the management of HE as well. However, neurotoxicity may be problematic so metronidazole is only considered as an alternative agent for HE.

Rifaximin 550 mg twice daily is effective in the treatment of HE.[13] It maintains remission better than lactulose alone and reduces the number of hospitalizations for HE as well; however, 90% of patients in this study received concomitant lactulose.[38] Rifaximin has also been shown in one study to decrease the incidence of overt HE in patients who underwent TIPS for intractable ascites or variceal bleeding prevention.[39]

Zinc is a cofactor for the urea cycle enzymes and is important for ammonia detoxification.[34] Zinc supplementation may be considered in patients with HE.[13] Zinc levels are frequently deficient in patients with cirrhosis. However, supplementation cannot be recommended in the absence of deficiency. Since zinc can inhibit copper absorption leading to anemia, care should be taken in recommending zinc unless truly indicated.

Drugs Affecting Neurotransmission

Flumazenil, a benzodiazepine receptor antagonist, may be considered for short-term therapy in refractory encephalopathy with suspected or confirmed benzodiazepine intake.

Treatment Recommendations: Hepatic Encephalopathy

⑦ The mainstay of therapy of HE involves measures to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose. Other adjunctive therapies include zinc replacement in patients with zinc deficiency and flumazenil in cases of refractory HE with the possibility of benzodiazepine use.

The target daily protein intake for patients with HE is recommended to be within 1.2 to 1.5 g/kg/day. Consideration may be made to substitute meat-source protein with vegetable or dairy protein. Supplementation with elemental zinc may be considered in patients with cirrhosis who are zinc deficient. A typical dose of elemental zinc is 50 mg/day.

In episodic HE, lactulose is initiated at a dose of 30 mL (20 g) orally every 1 to 2 hours until catharsis begins and the patient experiences one to two bowel movements. The dose is then adjusted to produce two to three soft stools per day for chronic therapy. Patients are monitored for changes to their electrolytes periodically as well as for changes in mental status.

Rifaximin 550 mg twice daily plus lactulose is superior to lactulose alone in patients with a history of recurrent HE.[38] Rifaximin is usually well tolerated. Because of its more favorable adverse effect profile, rifaximin is now considered the next line of therapy for recurrent HE over either metronidazole or neomycin.[13]

Systemic Complications

In addition to the more common complications of chronic liver disease discussed earlier, other complications can occur, including hepatorenal syndrome, hepatopulmonary syndrome, coagulation disorders, and endocrine dysfunction.

Hepatorenal syndrome, a functional renal failure in the setting of cirrhosis, occurs in the absence of structural kidney damage.[40] Portal hypertension leads to the release of vasodilators that results in blood pooling in the splanchnic vasculature reducing renal blood flow causing renal hypoperfusion. This causes activation of the renin-angiotensin-aldosterone system that results in severe renal vasoconstriction and fluid retention leading to ascites. As liver disease progresses, systemic vasodilation worsens and, subsequently, increased renal vasoconstriction occurs and renal blood flow is further decreased. The result is hepatorenal syndrome that can be separated into two main types. Type 1 occurs rapidly and has a precipitating cause such as SBP. Type 2 occurs more slowly and does not have a precipitating event.

Management of hepatorenal syndrome begins with discontinuing diuretics and any other medication that could potentially decrease effective blood volume and to expanding the intravascular volume with IV albumin at a dose of 1 g/kg up to a maximum of 100 g.[22,31,40] Precipitating factors, such as infection, fluid loss, and blood loss, should be investigated and treated if found.[40] Liver transplantation is the only definitive treatment for hepatorenal syndrome and the only therapy that will prolong survival. Medications used to bridge patients until transplantation includes arteriolar vasoconstrictor-based treatment with midodrine plus octreotide and IV albumin infusion as already discussed.

Hepatopulmonary syndrome affects up to 50% of patients with cirrhosis.[41] This abnormality is characterized by a defect in arterial oxygenation, which is caused by the pulmonary vascular dilatation that occurs in the presence of liver disease. These patients present with insidious onset of dyspnea, dyspnea upon standing, clubbing, and cyanosis. Patients with cirrhosis with these findings should be evaluated for hepatopulmonary syndrome, which is diagnosed based on the presence of arterial hypoxemia. Arterial hypoxemia is defined by measurements of the partial pressure of oxygen, testing for an increased alveolar–arterial oxygen gradient, and contrast-enhanced echocardiography. There is no effective medical management for hepatopulmonary syndrome. Liver transplantation offers the best chance for long-term recovery.

Patients with cirrhosis who are actively bleeding receive resuscitation with packed red blood cells targeting a hemoglobin of 7 to 9 g/dL (70-90 g/L; 4.34 to 5.59 mmol/L).[15,23] Platelet transfusion is used to maintain platelets over 50,000/mm^3 (50 × 10^9/L) during the period of active bleeding.[15] Cryoprecipitate to maintain fibrinogen levels over 100 mg/dL (1 g/L) is also usually recommended.

The presence of cirrhosis can produce abnormal circulating levels of various hormones.[42] Hypogonadism, diabetes mellitus, osteoporosis, and thyroid disorders are among the endocrine disorders that may develop related to advanced liver disease.

Liver Transplantation

The complications seen in patients with chronic liver disease are essentially secondary effects of the circulatory and metabolic changes that accompany liver failure. Unless the underlying etiology of a patient's fibrosis can be cured, cirrhosis generally progresses. Consequently, liver transplantation is often the only treatment that can offer a cure for the most severe complications of end-stage cirrhosis.

ALTERED DRUG PHARMACOKINETICS AND PHARMACODYNAMICS

Cirrhosis modulates the behavior of drugs in the body by inducing kinetic alterations in drug absorption, distribution, and clearance.[43] Patients with cirrhosis may exhibit pharmacodynamic changes with increased sensitivity to the effects of certain drugs including opiates, benzodiazepines, and nonsteroidal anti-inflammatory drugs (NSAIDs). These pharmacodynamic changes are separate and distinct from the enhancement of drug effects seen in patients with cirrhosis as a result of pharmacokinetic changes. The pathophysiologic changes that have particular impact on drug handling within the body include reduced liver blood flow, decreased first-pass extraction, systemic shunting, hypoalbuminemia, ascites, portal gastropathy, loss of cytochrome P450 enzymatic metabolic activity, reduced glutathione stores, impaired biliary excretion, and impaired renal excretion. Reduced hepatic blood flow, lower first-pass extraction, and portosystemic shunting result in higher bioavailability and serum levels of drugs. Hypoalbuminemia results in higher concentrations of free drug due to less protein binding. Ascites increases the volume of distribution of hydrophilic drugs. Serum levels of various drugs can be higher after normal dosing secondary to impaired biliary and renal excretion that is possible in cirrhosis. Reduced enzymatic clearance by hepatocytes can also lead to reduced first-pass metabolism and reduced hepatic clearance.

Drugs with a high extraction ratio (high-extraction drugs) are dependent on blood flow for metabolism, and the rate of metabolism will be sensitive to changes in blood flow. Drugs with a low extraction ratio (low-extraction drugs) are dependent on intrinsic metabolic activity for metabolism, and the rate of metabolism will reflect changes in intrinsic clearance and protein binding. Furthermore, hepatic biotransformation involves two types of metabolic processes: phase I and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule, such as sulfate or amino acid, rendering it more water soluble and enhancing its elimination. Drug metabolism by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.

The variability and complexity of the interaction between the extent and severity of liver disease and individual characteristics of the drug make it difficult to predict the degree of pharmacokinetic perturbation in an individual patient. There are no sensitive and specific clinical or biochemical markers that allow us to quantify the extent of liver insufficiency or degree of metabolic activity. In addition, renal insufficiency and alterations that commonly accompany cirrhosis further complicate empiric dosing recommendations in these patients. Dosing recommendations are most commonly nonspecific, with recommendations labeled for patients with mild-to-moderate liver impairment. Dosing information for patients with more severe liver impairment is not available. As a result, when patients with cirrhosis require therapy with drugs that undergo hepatic metabolism (eg, benzodiazepines), monitoring response to therapy and anticipating drug accumulation and enhanced effects is essential. In the case of benzodiazepines, selection of an agent such as lorazepam, an intermediate-acting agent that is metabolized via conjugation and has no active metabolites, is easier to monitor than a drug such as diazepam, a long-acting benzodiazepine that is oxidized in the liver and has an active metabolite with a long half-life of its own.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 55-5 summarizes the management approach for patients with cirrhosis and includes possible adverse drug effects. Cirrhosis is generally a chronic progressive disease that requires aggressive medical management to prevent or delay common complications. Table 55-5 also lists monitoring criteria that need to be carefully followed in order to achieve the maximum benefit from the medical therapies employed and prevent adverse effects. A therapeutic plan including therapeutic end points for each medical and diet therapy needs to be developed and discussed with patients who have cirrhosis.

ABBREVIATIONS

AASLD	American Association for the Study of Liver Diseases
ALT	alanine transaminase
AST	aspartate transaminase
EASL	European Association for the Study of the Liver
EVL	endoscopic variceal ligation
GABA	γ-aminobutyric acid
GGT	γ-glutamyl transpeptidase
HE	hepatic encephalopathy
HSC	hepatic stellate cell
HVPG	hepatic venous pressure gradient
INR	international normalized ratio
MDRO	multi-drug resistant organism
MELD	model for end-stage liver disease
PMN	polymorphonuclear
PT	prothrombin time
SAAG	serum-ascites albumin gradient
SBP	spontaneous bacterial peritonitis
TIPS	transjugular intrahepatic portosystemic shunt

SELF-ASSESSMENT QUESTIONS

1. A patient has the following information: albumin 4.1 g/dL (41 g/L), serum bilirubin 3.3 mg/dL (56.4 µmol/L), prothrombin time that is 5 seconds prolonged, no ascites, and no encephalopathy. In terms of Child-Pugh score, what is the patient's severity?

    A. Grade A

    B. Grade B

    C. Grade C

    D. Grade D

2. Your patient is a 64-year-old woman with marked abdominal distention and bulging flanks with dullness due to cirrhotic ascites. Which of the following diuretic options is most appropriate for this patient?

    A. Amiloride

    B. Eplerenone

    C. Hydrochlorothiazide

    D. Spironolactone plus furosemide

3. A 42-year-old male patient takes lactulose for hepatic encephalopathy which has been titrated to result in two to three loose bowel movements per day. He continues to experience symptoms of encephalopathy including drowsiness and obtundation. Which agent should be added next for this patient based on the information above?

    A. Ceftriaxone

    B. Neomycin

    C. Norfloxacin

    D. Rifaximin

4. Your patient has been evaluated and it has been determined that medication management to prevent the first occurrence of variceal bleeding is indicated. Which of the following represents an appropriate recommendation for this patient?

    A. Atenolol

B. Bisoprolol

C. Metoprolol

D. Nadolol

5. Which of the following represents an appropriate goal for a patient started on propranolol for variceal bleeding prophylaxis?

   A. Heart rate of 55 to 60 beats/min; diastolic blood pressure > 90 mm Hg

   B. Heart rate of 55 to 60 beats/min; systolic blood pressure > 90 mm Hg

   C. Heart rate of 60 to 65 beats/min; diastolic blood pressure > 90 mm Hg

   D. Heart rate of 60 to 65 beats/min; systolic blood pressure > 90 mm Hg

6. A patient who develops type 2 hepatorenal syndrome may be managed with which of the below combinations as bridge to transplant?

   A. Albumin + cefotaxime + rifaximin

   B. Albumin + midodrine + octreotide

   C. Carvedilol + furosemide + spironolactone

   D. Lactulose + rifaximin + midodrine

7. A patient was successfully treated for an episode of spontaneous bacterial peritonitis (SBP). Which option is the most appropriate antibiotic as indefinite therapy for secondary prophylaxis of SBP?

   A. Metronidazole

   B. Neomycin

   C. Ceftriaxone

   D. Ciprofloxacin

8. A 47-year-old woman with a history of alcoholic cirrhosis is admitted to the hospital and the team plans to initiate empiric therapy for spontaneous bacterial peritonitis. Which one of the following options is the best course of action for initiation?

   A. Albumin

   B. Cefotaxime

   C. Vancomycin plus tobramycin

   D. Trimethoprim/sulfamethoxazole

9. A patient presents to the emergency department with moderate hepatic encephalopathy. In addition to supportive care, which medication would be first-line therapy to reduce nitrogenous load?

   A. Lactulose

   B. Metronidazole

   C. Neomycin

D. Rifaximin

10. Which medication should be discontinued in a patient with cirrhosis and ascites?

    A. Furosemide

    B. Nadolol

    C. Naproxen

    D. Spironolactone

11. A patient is admitted to the hospital, requiring management of acute variceal hemorrhage. The patient has a history of myocardial infarction (6 months ago). Which medication is the best intervention to decrease portal blood flow and pressure?

    A. Nitroglycerin

    B. Octreotide

    C. Carvedilol

    D. Vasopressin

12. A 42-year-old male patient presented to the emergency department with large bleeding varices, based on an esophagogastroduodenoscopy. Which goal would be the most appropriate based on the patient's condition?

    A. Achieve a systolic blood pressure of 80 mm Hg with fluid resuscitation

    B. Intake a target of 1.2 to 1.5 g/kg/day of protein

    C. Maintain a hemoglobin concentration of 7 to 9 g/dL (70-90 g/L; 4.34-5.59 mmol/L)

    D. Restrict sodium intake to 2,000 mg/day

13. A patient is prescribed and adherent with spironolactone plus furosemide for ascites. Concentration of which of the following will be greater than the concentration of potassium on a spot urine collection if the patient is meeting goal for their diuretic therapy?

    A. Chloride

    B. Creatinine

    C. Glucose

    D. Sodium

14. Which of the following is a laboratory abnormality possibly indicative of cirrhosis?

    A. Hyperalbuminemia

    B. Low alkaline phosphatase

    C. Low prothrombin time

    D. Thrombocytopenia

15. Drugs metabolized through which of the following processes are most likely to be affected by cirrhosis?

    A. Conjugation

B. Hydrolysis

C. Oxidation

D. Sulfation

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The patient will receive 3 points for bilirubin over 3 mg/dL (51.3 µmol/L), 1 point for albumin>3.5 g/dL (35 g/L), 1 point for no ascites, 1 point for no encephalopathy, and 2 points for prothrombin time prolonged between 4 and 6 seconds. This makes their total score 8 points which corresponds to a Grade of B.

2. **D.** Spironolactone plus furosemide is likely the most appropriate selection for diuretic therapy in a patient with ascites due to cirrhosis. The combination promotes effective sodium excretion and diuresis while maintaining eukalemia.

3. **D.** Patients with intolerance to or insufficient resolution of encephalopathy symptoms should have rifaximin added to continuing lactulose therapy. Rifaximin has replaced neomycin and metronidazole for add-on owing to its superior tolerability and more favorable side effect profile.

4. **D.** Nadolol, propranolol, and carvedilol are recommended options for primary prophylaxis against gastroesophageal bleeding. Nonselective β-adrenergic blockers are recommended for this indication as they reduce portal pressure by reducing cardiac output and, most importantly, through their β_2 action leading to splanchnic vasoconstriction reducing portal blood flow.

5. **B.** A suggested target for β-adrenergic blocker therapy, when used as prophylaxis against variceal bleeding, is a heart rate of 55 to 60 beats/minute. Systolic blood pressure should be maintained above 90 mm Hg as the risk for inadequate perfusion leading to complications like hepatorenal syndrome is a concern with hypotension.

6. **B.** Once severe complications of cirrhosis occur, such as hepatorenal syndrome, patients should be evaluated for transplantation as other therapeutic options, including midodrine plus octreotide and albumin, are only temporary measures that may be instituted to “bridge” a patient until transplantation can occur.

7. **D.** Patients who have survived an episode of spontaneous bacterial peritonitis should receive indefinite secondary prophylaxis against another episode. An appropriate antibiotic choice would be ciprofloxacin for this indication.

8. **B.** Appropriate empiric therapy for suspected acute spontaneous bacterial peritonitis requires an antibiotic and, for patients with cirrhosis, the most appropriate choice is cefotaxime. Vancomycin plus tobramycin represents too broad a spectrum of bacterial coverage. Trimethoprim/sulfamethoxazole is not recommended for primary treatment or secondary prophylaxis of SBP.

9. **A.** Lactulose is the first-line drug therapy option used to reduce circulating systemic nitrogenous waste. Rifaximin may be added to lactulose or used in patients unable to tolerate lactulose. Metronidazole and neomycin are no longer preferred options for add-on and are not recommended as initial therapy.

10. **C.** Patients with ascites should avoid use of nonsteroidal anti-inflammatory drugs such as naproxen. Furosemide and spironolactone will be fundamental therapies in the management of ascites. β-Adrenergic blocker therapy can be used in patients with ascites, but reductions in dose for both propranolol and nadolol are recommended when ascites is present. Appropriate blood pressure maintenance, ensuring that systolic blood pressure remains above 90 mm Hg, is important.

11. **B.** Octreotide is the recommended splanchnic vasoconstrictor for patients with acute variceal bleeding. Vasopressin is not preferred and nitroglycerin is not an appropriate choice for this indication. Carvedilol represents an option for primary prophylaxis against variceal bleeding but is not an appropriate choice for the treatment of acute bleeding.

12. **C.** An appropriate goal of therapy for acute variceal bleeding is hemoglobin of 7 to 9 g/dL (70-90 g/L; 4.34-5.59 mmol/L). While maintaining an appropriate blood pressure will also be important, fluid resuscitation alone may be insufficient if blood loss is severe. Maintenance of an appropriate daily protein intake is a target for encephalopathy rather than acute variceal bleeding. Restriction of sodium intake is an appropriate goal relative to

the management of ascites.

13. **D.** A random spot urine sodium concentration that is greater than the potassium concentration correlates well with a 24-hour urinary sodium excretion over 78 mmol/day and is an easier test to complete.

14. **D.** Thrombocytopenia typically accompanies cirrhosis. Hypoalbuminia, elevated alkaline phosphatase, and elevated prothrombin time would be anticipated.

15. **C.** Enzymatic metabolism by hepatocytes is most likely to be impacted by cirrhosis. This represents an impairment in oxidation. Other metabolic processes, including conjugation, hydrolysis, and sulfation, are impacted to a lesser extent than oxidation.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 57: Pancreatitis

Scott Bolesta

KEY CONCEPTS

KEY CONCEPTS

ACUTE PANCREATITIS

① Factors that can contribute to acute pancreatitis should be identified and corrected, including discontinuation of medications that could be potential causes.

② Patients with acute pancreatitis should receive goal-directed fluid management to reduce the risks of persistent systemic inflammatory response syndrome (SIRS) and organ failure.

③ Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis despite a lack of high-quality evidence to support the practice.

④ Use of prophylactic antibiotics is not recommended in patients with acute pancreatitis without signs or symptoms of infection, including those with predicted severe acute pancreatitis or necrotizing pancreatitis.

CHRONIC PANCREATITIS

⑤ Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark symptoms and complications of chronic pancreatitis.

⑥ Pain from chronic pancreatitis may initially be treated with nonopioid analgesics, but adjuvant agents may be necessary as the disease progresses.

⑦ Pancreatic enzyme and fat-soluble vitamin supplementation are the primary treatments for malabsorption due to chronic pancreatitis.

⑧ Enteric-coated pancreatic enzyme supplements are the preferred dosage form in the treatment of malabsorption and steatorrhea due to chronic pancreatitis.

⑨ The addition of a histamine-2 receptor antagonist or proton pump inhibitor to pancreatic enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and steatorrhea due to chronic pancreatitis.

BEYOND THE BOOK

BEYOND THE BOOK

1. Robert Whipple is a 48-year-old man admitted to the intensive care unit (ICU) for acute pancreatitis. He weighs 89 kg. He has no signs or symptoms of infection. Which resuscitation fluid would you recommend for Mr. Whipple and why? What volume and rate of infusion would you recommend for his resuscitation fluid? What are the endpoints you recommend monitoring to determine adequate fluid resuscitation? These are the key decisions regarding the assess, plan, implement, and monitor aspects of the Pharmacist Patient Care Process concerning fluid resuscitation in patients with acute pancreatitis.
2. Using available resources, determine the monthly cash prescription payment for a patient with exocrine pancreatic insufficiency from chronic pancreatitis who requires 60,000 USP units of lipase with each meal; the patient eats five meals a day, along with three snacks. Do this for all Food and Drug Administration (FDA)-approved pancrelipase products available in the United States. How would this information affect your recommendation of a pancrelipase product for this patient? Now locate the online formulary of a third-party prescription plan in your area. Determine if the plan's coverage of the same pancrelipase products alters your decision in any way. This activity is to make you aware of not only the pill burden of patients with exocrine pancreatic insufficiency but also the cost related to these medications.

INTRODUCTION

Pancreatitis is inflammation of the pancreas with variable involvement of regional tissues or remote organ systems.[1,2] Acute pancreatitis is characterized by severe pain in the upper abdomen and elevations of pancreatic enzymes in the blood.[3,4] In the majority of patients, acute pancreatitis is a self-limiting disease that resolves spontaneously without complications. Approximately 20% of adults with acute pancreatitis have a severe course.[3] While the overall mortality of acute pancreatitis is low, severe pancreatitis is associated with a mortality as high as 40%.[3,5,6] The risk for progression to chronic pancreatitis after an initial episode of acute pancreatitis is related to the etiology. Patients with acute pancreatitis due to gallstone disease have little risk for progression to chronic disease whereas patients with alcohol-related acute pancreatitis have a risk of 13% to 38% based on whether or not they continue to consume alcohol.[7]

Chronic pancreatitis is characterized by long-standing inflammation that eventually leads to a loss of pancreatic exocrine and endocrine functions.[8–11] It is a progressive disease that often goes unnoticed for many years. The usual initial presentation is complaints of chronic abdominal pain. Later in the disease process malabsorption with resultant steatorrhea occurs. This leads to malnutrition and weight loss. Finally, patients develop diabetes mellitus due to a loss of pancreatic endocrine function.[8,9,11]

EPIDEMIOLOGY

Acute pancreatitis is one of the most common gastrointestinal disorders causing hospitalization in the United States with admission rates of approximately 13 to 45 per 100,000 per year.[3,5,7] The incidence of hospitalization has increased with a 13.3% rise occurring within the first decade of the century.[12] The risk for acute pancreatitis varies widely with geographic, etiologic (eg, alcohol consumption and smoking), environmental, and genetic factors. In adults and children, the increase in acute pancreatitis is often attributed to rising rates of obesity.[4,13] The annual incidence of chronic pancreatitis in the United States is 5 to 14 per 100,000, and the prevalence is 42 to75 per 100,000.[8,10,11] The prevalence increases with age, with an average onset in the fifth to sixth decade of life, and it is 4.5 times more common in males than females.[8,10,11] Also, the prevalence of chronic pancreatitis varies widely based on geographic location.[9] There is also racial disparity with the disease, with Black patients having 2 to 3 times the risk than White patients, and being more than twice as likely to be hospitalized.[8,10,11]

PANCREATIC EXOCRINE PHYSIOLOGY

The pancreas possesses both endocrine and exocrine functions. The islets of Langerhans, which contain the cells of the endocrine pancreas, secrete insulin, glucagon, somatostatin, and other polypeptide hormones. The exocrine pancreas is composed of acini and ductules that secrete about 2.5 L/day of isotonic fluid that contains water, electrolytes, and pancreatic enzymes necessary for digestion. Bicarbonate and other electrolytes are secreted primarily by the centroacinar (ductular) cells in order to neutralize gastric acid. Pancreatic juice is delivered to the duodenum via the pancreatic ducts (Fig. 57-1) where the alkaline secretion neutralizes gastric acid and provides an appropriate pH for maintaining the activity of pancreatic enzymes.[14]

FIGURE 57-1

Anatomic structure of the pancreas and biliary tract.

The major pancreatic exocrine enzyme groups are as follows:

1. Amylolytic: α-amylase
2. Lipolytic: lipase, procolipase, prophospholipase A2, and carboxylesterase
3. Proteolytic: trypsinogens, chymotrypsinogen, procarboxypeptidase A and B, proelastase and mesotrypsin
4. Nucleolytic: ribonuclease and deoxyribonuclease
5. Other: trypsin inhibitor

Amylase is responsible for digestion of starches and glycogen through hydrolysis. The lipolytic enzymes break down triglycerides, cholesterol, and other fats in the digestive tract. Specifically, lipase hydrolyzes triglycerides into fatty acids and monoglycerides. Colipase and bile acids facilitate this process by allowing lipase to act on the hydrophobic surface of fat droplets in the mainly hydrophilic environment. Phospholipase A2 and carboxylesterase continue to break down fatty acids, cholesterol, monoglycerides, and other products of fat digestion. Proteolytic enzymes digest proteins into oligopeptides and free amino acids, while nucleases break down nucleic acids.[14]

The production of proteolytic enzymes in the pancreas occurs in a manner that prevents self-digestion of the pancreas. These enzymes are synthesized within the acinar cells, stored in vacuoles, and secreted into the duodenum as zymogens (inactive enzymes). Enterokinase secreted by the duodenal mucosa converts trypsinogen to trypsin, which then activates all other proteolytic zymogens along with procolipase and prophospholipase A2. Thus, two important mechanisms protect the pancreas from the potential degradative action of its own digestive enzymes. First, the synthesis of proteolytic enzymes as zymogens requires extrapancreatic activation by trypsin. Second, pancreatic juice contains a low concentration of trypsin inhibitor, which inactivates any autocatalytically formed trypsin within the pancreas. Proteolytic activity of trypsin in the intestinal lumen is not inhibited because the concentration of trypsin inhibitor is minimal. Lipase, amylase, ribonuclease, and deoxyribonuclease are secreted by the acinar cells in their active form.[14]

The regulation of exocrine pancreatic secretion is a complex interplay of neurohormonal feedback with three distinct phases. The first phase is the cephalic phase where the sight, smell, and taste of food cause pancreatic enzyme secretion through stimulus of the vagus nerve. Vasoactive intestinal peptide (VIP) and gastrin-releasing peptide released from efferent vagus nerve terminals bind to receptors on the acinar cells stimulating enzyme release.[14] Water and bicarbonate are also released from ductal cells due to VIP stimulation. The gastric phase occurs due to gastric distension from food entering the stomach. This results primarily in secretion of digestive enzymes from the pancreas. Once chyme enters the duodenum, the intestinal phase begins. The chyme causes secretin to be released from the duodenal mucosa when its pH is less than 4.5. Secretin results in water and bicarbonate secretion from the pancreas to increase intestinal pH for stable lipolytic enzyme activity. Digestive enzymes are released from the pancreas due to the presence of fatty acids, peptides, amino acids, and glucose in the duodenum.[14]

The feedback mechanism for continued release of pancreatic enzymes involves the hormone cholecystokinin (CCK). When products of fat, protein, and starch digestion enter the upper small intestine, they stimulate the release of CCK from I cells into the blood. Elevated levels of CCK in the serum activate a vasovagal reflex causing further release of VIP and gastrin-releasing peptide, leading to enhanced pancreatic enzyme secretion. Inhibition of this feedback loop is thought to be due to trypsin. After digestion is complete, unoccupied trypsin is thought to inhibit the release of CCK.[14] A more in-depth discussion of pancreatic physiology can be found elsewhere.[14]

ACUTE PANCREATITIS

Acute pancreatitis may be mild or may be associated with complications including organ failure and pancreatic necrosis. Prognosis and management vary according to the severity of the disease. There are several causes of acute pancreatitis, but the most common are obstruction due to gallstones and alcohol-induced pancreatitis. Patients generally present with abdominal pain and other gastrointestinal symptoms with diagnosis being made based on presenting signs and symptoms, lab abnormalities, and imaging studies as necessary. Treatment focuses on providing fluid resuscitation and treating the pain and complications associated with acute pancreatitis.

Etiology

Table 57-1 lists the etiologic risk factors associated with acute pancreatitis. Obstruction caused by gallstones is the most common cause of acute pancreatitis in the United States, with alcohol misuse being the second most common. Abdominal obesity increases the risk for both gallstone- and nongallstone-related acute pancreatitis. Moderate elevations in lipid levels are associated with nonalcohol-related pancreatitis, and smoking has emerged as a strong risk.[4,7,12,13,15] There is also an autoimmune form of pancreatitis.[3,7] Diabetes mellitus is also associated with an increase in acute pancreatitis as are autoimmune disorders such as inflammatory bowel disease.[3,7,13,16,17] Most remaining cases are classified as idiopathic.[4,13] Acute pancreatitis can occur as a result of undergoing an endoscopic retrograde cholangiopancreatography (ERCP) with overall rates up to 5%.[4,7] Pregnancy is not considered a cause of acute pancreatitis; however, pregnant women develop pancreatitis as a result of a coincident process, most commonly cholelithiasis.[18] The reported incidence of acute pancreatitis in children has increased in recent years, and the common etiologies are biliary disease, systemic illness, medications, trauma, and idiopathic.[19,20]

TABLE 57-1

Etiologic Risk Factors Associated with Acute Pancreatitis

Structural	Gallstone disease, sphincter of Oddi dysfunction, pancreas divisum, pancreatic tumors
Toxins	Alcohol (ethanol) consumption, scorpion bite, organophosphate insecticides
Infectious	Bacterial, viral (including HIV and H1N1 influenza), parasitic
Metabolic	Hypertriglyceridemia, chronic hypercalcemia
Genetic	Cystic fibrosis, α1-antitrypsin deficiency, hereditary (trypsinogen gene mutations)
Medications	See Table 57-2 for specific drugs
Iatrogenic	Abdominal surgery, ERCP
Kidney disease	Chronic kidney disease, dialysis-related
Trauma	Blunt abdominal trauma
Vascular	Vasculitis, atherosclerosis, cholesterol emboli, coronary artery bypass surgery
Other etiologies	Congenital, Crohn’s disease, autoimmune, tropical, solid organ transplantation (eg, liver, kidney, heart), refeeding syndrome
Idiopathic	Undetermined cause

HIV, human immunodeficiency virus; ERCP, endoscopic retrograde cholangiopancreatography.

Data from References 3,4,7,13.

Medications

① Factors that can contribute to acute pancreatitis should be identified and corrected, including discontinuation of medications that could be potential causes. Drug-induced acute pancreatitis should be considered when other causes have been excluded and there is a temporal relationship with the initiation of a medication that has been implicated as a cause. Most experts consider drug-induced pancreatitis to be rare, although some reports include higher estimates.[4,7,13] The difficulty in diagnosing drug-induced pancreatitis has led to an underestimation of the rate.[13] Most information on drug-induced acute pancreatitis is obtained from case reports, which do not provide reliable information on incidence. The most convincing case reports involve recurrence on rechallenge; however, rechallenge is rare, occurring only when alternative therapy is not available. Further complicating the evaluation of some reports is the use of medications associated with pancreatitis in patient populations with an increased risk of pancreatitis.[13] Adverse events attributed to newly introduced medications may be reported more frequently.[21] Many medications have been frequently reported to cause acute pancreatitis. Patients with human immunodeficiency virus (HIV) have an increased risk of pancreatitis and there are many reports of pancreatitis attributed to antiretroviral agents.[4,7,13,21] Pancreatitis due to azathioprine is reported more frequently in patients with

Crohn's disease than in patients taking the medication for other indications, suggesting an interaction between the disease and medication. Patients with Crohn's disease often take other medications that can cause pancreatitis, including 5-aminosalycilates, corticosteroids, and sulfasalazine.[24] Patients with type 2 diabetes mellitus have an increased risk of acute pancreatitis. Case reports and some observational studies have linked antihyperglycemic agents, including metformin, sulfonylureas, and incretin mimetics, with pancreatitis. There is no increase in pancreatitis with incretin mimetics compared to sulfonylureas, metformin, or insulin.[25,26] Mixed results have been reported in meta-analyses evaluating the risk of pancreatitis from dipeptidyl peptidase-4 inhibitors.[26,27] Complicating comparisons between agents used to treat diabetes mellitus is that the medications are often used in obese patients and patients with different durations of disease, both of which may also influence disease-associated pancreatitis.[28] Polypharmacy is associated with an increased risk of acute pancreatitis.[29]

The onset of drug-induced pancreatitis after initiation of medications ranges from a few months to several years, with a median of 5 weeks; onset after rechallenge can occur within hours. The onset may differ according to the mechanism. Clinicians should be especially suspicious of a drug as a cause of acute pancreatitis in high-risk patients, such as those receiving immunomodulating drugs or who have HIV infection, the elderly, or those with diabetes mellitus.[23]

Mechanisms of drug-induced pancreatitis have been proposed for some medications but remain poorly defined. Possible mechanisms include direct toxic effects of the drug or its metabolites, hypersensitivity, drug-induced hypertriglyceridemia, and alterations of cellular function in the pancreas and pancreatic duct.[22] Ultimately, drug-induced pancreatitis causes damage to the pancreas, which produces a response similar to other causes of pancreatitis. It is prudent to withdraw a medication when an association is suspected.

Numerous drugs are believed to cause acute pancreatitis, but ethical and practical considerations often prevent rechallenge with suspected agents. Table 57-2 lists specific agents associated with acute pancreatitis. Classification schemes consider rechallenge, the number of case reports, consistency with respect to the onset of symptoms following initiation of the suspect medication, and exclusion of other causes.

Pathophysiology

The pathophysiology of acute pancreatitis is based on events that initiate injury and secondary events that establish and perpetuate the injury (Fig. 57-2). Gallstones, alcohol misuse, and other causes of pancreatitis produce different initial insults to the pancreas. However, the resulting pathophysiologic process may be similar and include autodigestion, abnormal acinar calcium signaling, and inflammatory response. In acinar cells, the separation of zymogens and lysosomes can be disrupted, resulting in exposure of trypsinogen to lysosomal enzymes such as cathepsin B. The premature activation of trypsinogen to trypsin within the pancreas leads to activation of other digestive enzymes and autodigestion of the gland.[4,7]

In addition to activation of digestive enzymes within the pancreas, enzymes are also released into surrounding fat, vascular endothelium, and other surrounding tissues and structures causing further damage and necrosis. Lipase damages fat cells, producing noxious substances that cause further pancreatic and peripancreatic injury. There may be an independent response from intra-acinar activation of inflammatory factors. The release of cytokines by acinar cells directly causes their injury and enhances the inflammatory response.[30] Injured acinar cells liberate chemoattractants that recruit neutrophils, macrophages, and other cells to the area of inflammation. These immune responses cause a systemic inflammatory response syndrome (SIRS). Vascular damage and ischemia causes the release of kinins, which makes capillary walls permeable and promotes tissue edema. Finally, pancreatic infection may result from increased intestinal permeability and translocation of colonic bacteria.[30]

Clinical Presentation

Signs and Symptoms

The clinical presentation of acute pancreatitis varies depending on the severity of the inflammatory process and whether damage is confined to the pancreas or involves local and systemic complications (Table 57-3).[7]

TABLE 57-3

Presentation and Diagnosis of Acute Pancreatitis

General

- The patient may have acute mild symptoms or present with a severe acute attack with life-threatening complications.

Symptoms

- The patient may present initially with moderate abdominal discomfort to excruciating pain, nausea, shock, and respiratory distress.
- Abdominal pain occurs in 95% of patients. The pain is usually epigastric and radiates to either of the upper quadrants or the back in two-thirds of patients. In gallstone pancreatitis, the pain is typically sudden and quite severe and the intensity is often described as “knife-like” or “boring.” The pain usually reaches its maximum intensity within 30 minutes and may persist for hours or days. Repositioning the patient relieves very little of the pain. In alcohol misuse and other cases, the onset of pain may be less abrupt and poorly localized. Pain may not be the dominant symptom if it is masked by multiorgan failure.
- Nausea and vomiting occur in 85% of patients and usually follow the onset of abdominal pain. Vomiting does not provide relief of the abdominal pain.

Signs

- Marked epigastric or diffuse tenderness on palpation with rebound tenderness and guarding in severe cases. The abdomen is often distended and tympanic, with bowel sounds decreased or absent in severe disease.
- Vital signs may be normal, but hypotension, tachycardia, and low-grade fever are often observed, especially with widespread pancreatic inflammation and necrosis.
- Dyspnea and tachypnea are often signs of acute respiratory complications. Jaundice and altered mental status may be present and have multiple causes. Other signs of alcohol-induced liver disease may be present in patients with alcohol-induced pancreatitis.

Laboratory tests

- Leukocytosis is frequently present; hyperglycemia or hypoalbuminemia may be present. Liver transaminases, alkaline phosphatase, and bilirubin are usually elevated in gallstone pancreatitis and in patients with intrinsic liver disease. Elevated serum triglycerides may also be a possible etiology.
- The hematocrit may be normal, but hemoconcentration results from multiple factors (eg, vomiting). In patients with third-space fluid loss, hemoconcentration is present and a reasonably accurate marker of severe disease. A hematocrit of greater than 44% predicts severe acute pancreatitis. Further, failure to reverse hemoconcentration has been associated with pancreatic necrosis.
- Blood urea nitrogen (BUN) that is elevated (greater than 20 mg/dL [7.1 mmol/L]) or rising over the first 24 hours has been associated with increased mortality.
- The total serum calcium is usually normal initially, but hypocalcemia disproportionate to the hypoalbuminemia may develop. Marked hypocalcemia is an indication of severe necrosis and a poor prognostic sign.
- The serum amylase concentration usually rises within 4-8 hours of the initial attack, peaks at 24 hours, and returns to normal over the next 8-14 days. Serum amylase concentrations greater than three times the upper limit of normal are highly suggestive of acute pancreatitis. Persistent elevations suggest extensive pancreatic necrosis and related complications. Normal concentrations may be observed if testing is delayed (ie, amylase may have returned to normal) or in patients with hyperlipidemic pancreatitis (ie, marked triglyceride elevations may interfere with amylase assay). In addition, many nonpancreatic diseases may be associated with hyperamylasemia, including salivary, kidney, hepatobiliary, metabolic, female reproductive tract, and neoplastic diseases.
- Serum lipase is specific to the pancreas and concentrations are elevated and parallel the elevations in serum amylase. Levels remain elevated with pancreatic inflammation and return to normal when the inflammatory process resolves. Because of its longer half-life, elevations of serum lipase can be detected after the serum amylase has returned to normal.
- Additional biomarkers: C-reactive protein is a widely available test and levels greater than 190 mg/L at 48 hours predict severe acute pancreatitis.

Abdominal imaging

- Transabdominal ultrasound should be performed in all patients to detect dilated biliary ducts and stones in the gallbladder.
- CECT is used if the diagnosis cannot be made from clinical and laboratory findings. It is less accurate for evaluating the gallbladder and biliary ducts. The test distinguishes interstitial from necrotizing pancreatitis, but does not distinguish between fat necrosis and acute fluid collection. Tests that are performed in the first few days may miss necrosis. Tests should be performed at least 72-96 hours after symptom onset; tests performed too early may result in unnecessary exposure to risk and increased cost.
- Magnetic resonance imaging is used to grade the severity of acute pancreatitis, identify biliary duct problems that are not seen on CT, or if there are contraindications to CECT. Patients over the age of 40 with pancreatitis of an unknown etiology should be evaluated for pancreatic malignancy with CT or endoscopic ultrasonography.

APACHE, Acute Physiology and Chronic Health Evaluation; CECT, contrast-enhanced computed tomography; CT, computed tomography.

Data from References 4,7,13,30.

Diagnosis

The diagnosis of acute pancreatitis requires two of the following three: upper abdominal pain, a serum lipase or amylase concentration at least three times greater than the upper limit of normal, or characteristic findings on imaging studies.[3,4,13] Lipase is more sensitive and specific than amylase and is the preferred laboratory test. Although used in the diagnosis of acute pancreatitis, the degree of amylase and lipase elevations is not predictive of patient outcome. Imaging studies are not necessary for diagnosis if the other two findings are positive. Contrast-enhanced computed tomography (CECT) of the abdomen may be used to confirm the diagnosis in patients with amylase or lipase that is not three times the upper limit of normal, or in sedated patients. Patients should be monitored for SIRS organ failure for the first 48 hours.[3,13] For further information on laboratory tests and abdominal imaging, refer to Table 57-3. Pertinent history includes previous history of pancreatitis, gallstone disease, alcohol use, medication use, recent surgery or ERCP, hyperlipidemia, recent infections, trauma, and family history. Magnetic resonance cholangiopancreatography (MRCP) is useful for detecting retained common bile duct stones. Laboratory tests should include liver enzymes, triglycerides, and calcium. Transabdominal ultrasound of the right upper quadrant is recommended to assess for gallstones.[3,4,7,13]

Acute pancreatitis is categorized according to the revised Atlanta classification. The revised Atlanta Classification defines acute pancreatitis as mild disease (not associated with organ failure, local complications, or systemic complications), moderately severe (transient organ failure, local complications or systemic complications), and severe (persistent organ failure).[3,7,13,31] An alternative classification system was proposed by an international multidisciplinary group using factors that have a causal association with severity (ie, distant organ failure or pancreatic necrosis) rather than events that may be associated with severity.[3,7,13,32] This determinant-based classification includes mild (no organ dysfunction or necrosis), moderate (sterile necrosis or transient organ dysfunction or both), severe (either infected necrosis or persistent organ dysfunction), and critical (infected necrosis and persistent organ dysfunction).

Prediction of severity of acute pancreatitis is useful for decisions involving the need for aggressive treatment, including admission to an ICU.[2,4,13] Multiple scoring systems have been developed to predict which patients with acute pancreatitis are at greatest risk for persistent organ failure.[2,4,13] Validated systems include the Acute Physiologic and Chronic Health Evaluation II (APACHEII) system, Bedside Index of Severity in Acute Pancreatitis, Harmless Acute Pancreatitis Score, the Ranson criteria, Japanese Severity Score, Pancreatitis Outcome Prediction, and Modified Glasgow Acute Pancreatitis Severity Score. They are used in determining aggressiveness of initial therapy as well as in developing clinical trials of interventions. However, development and validation of such systems remain an ongoing area of research. BISAP and APACHE II were similar in predicting severity of pancreatitis, organ failure and mortality.[33,34] Despite this, many are too complicated for bedside use or rely on measurements that are not widely available.[4] Also, some scoring systems have not been validated in prospective trials or have poor predictive ability.[3,13] The American Gastroenterological Association guidelines note a lack of demonstrated clinical benefit from the scoring systems and supports the use of a combination of clinical judgment and a variety of scoring tools.[2]

Clinical Course and Prognosis

The clinical course of acute pancreatitis varies from a mild transitory disorder to severe necrotizing disease. Mild acute pancreatitis is self-limiting and subsides spontaneously within 3 to 5 days. Mortality is influenced by etiology, as idiopathic and postoperative acute pancreatitis have higher rates than gallstone- or alcohol-related disease. First and second occurrences also carry a higher mortality than subsequent episodes. Mortality increases with unfavorable early prognostic signs, local complications, and organ failure. Persistent organ failure is a greater risk than transient organ failure.[6] Severe pancreatitis with either organ failure or infected necrosis is associated with a mortality of approximately 30%, and increases when both are present.[3,4,6,7,13]

Complications

Early complications are a result of SIRS and organ failure. The most common systemic complication of acute pancreatitis is respiratory failure.[4,13,21] In addition, patients may experience systemic complications due to exacerbation of preexisting renal, lung, or heart disease.[13,31] A second phase occurs in patients with moderately severe or severe disease. These patients have persistent organ failure and may have local complications including interstitial pancreatitis (acute peripancreatic fluid collection and pancreatic pseudocysts) and collection of necrosis. These develop approximately 3 to 4 weeks after the initial attack.[3,4,13] Long-term complications include recurrence of acute pancreatitis, development of pancreatic exocrine and endocrine insufficiency, and progression to chronic pancreatitis.[3,4,13,35] Exocrine and endocrine insufficiency develops in approximately 20% to 30% of patients following acute pancreatitis, with about one-third of those patients progressing to chronic pancreatitis.[3,4,13,36] Some patients with peripancreatic necrosis will develop secondary infections that usually require invasive intervention.[3,13]

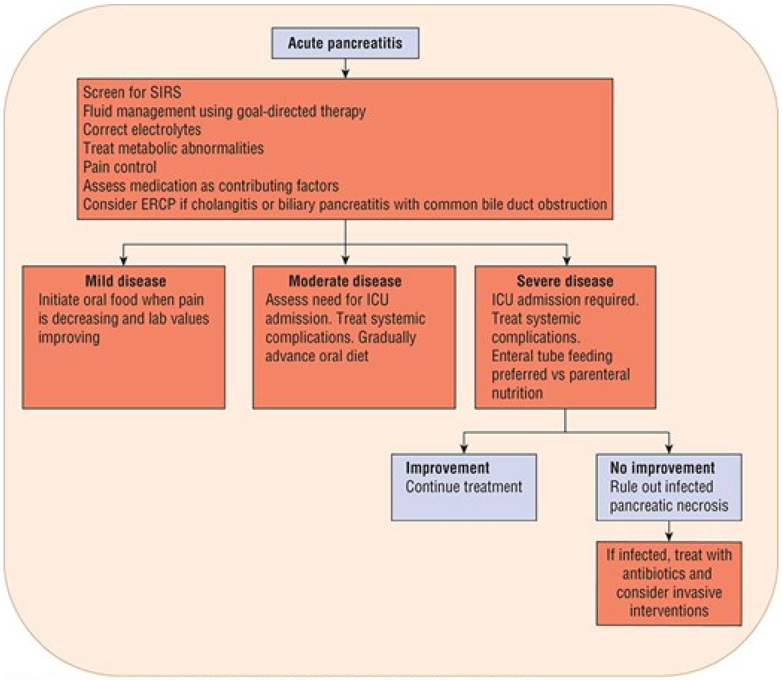
TREATMENT

Desired Outcome

Treatment of acute pancreatitis is aimed at relieving abdominal pain and nausea, replacing fluids, correcting electrolyte, glucose, and lipid abnormalities, minimizing systemic complications, and managing pancreatic necrosis and infection. Management varies depending on the severity of the attack (Fig. 57-3). Patients with mild acute pancreatitis respond very well to the initiation of supportive care. Patients with severe acute pancreatitis should be treated aggressively and monitored closely.

FIGURE 57-3

Algorithm of guidelines for evaluation and treatment of acute pancreatitis. (SIRS, systemic inflammatory response syndrome; ERCP, endoscopic retrograde cholangiopancreatography; ICU, intensive care unit)



Acute pancreatitis
Screen for SIRS
Fluid management using goal-directed therapy
Correct electrolytes
Treat metabolic abnormalities
Pain control
Assess medication as contributing factors
Consider ERCP if cholangitis or biliary pancreatitis with common bile duct obstruction
Mild disease
Initiate oral food when pain is decreasing and lab values improving
Moderate disease
Assess need for ICU admission. Treat systemic complications. Gradually advance oral diet
Severe disease
ICU admission required. Treat systemic complications. Enteral tube feeding preferred vs parenteral nutrition
Improvement
Continue treatment
No improvement
Rule out infected pancreatic necrosis
If infected, treat with antibiotics and consider invasive interventions

General Approach to Treatment

All patients with acute pancreatitis should receive supportive care, including IV fluid resuscitation, adequate nutrition, and effective relief of pain and nausea. Patients should be evaluated for admission to the ICU. Patients predicted to follow a severe course may require treatment of systemic complications.[3,4] Fluid therapy is recommended and may help prevent organ failure.[1,2] Patients with pancreatitis and SIRS should be treated according to SIRS guidelines. IV potassium, calcium, and magnesium are used to correct electrolyte deficiency states. Insulin is used to treat hyperglycemia. Local complications resolve as the inflammatory process subsides. However, patients with necrotizing pancreatitis may require procedural intervention.[37] Medications listed in Table 57-2 should be reviewed and discontinued if other etiologies are unlikely.

Nonpharmacologic Therapy

Nonpharmacologic therapy includes ERCP for removal of any underlying biliary tract stones, procedural interventions, and nutritional support. The need for admission to an ICU should be addressed. Advances in minimally invasive surgical techniques are changing practice with respect to timing and approach to managing infected necrotizing pancreatitis, and may help lower the risk of mortality in the most critical patients.[2,37] Patients with alcohol-related pancreatitis should receive abstinence interventions during the inpatient stay.[1]

Nutrition and Probiotics

Nutritional support plays an important role in the management of patients with mild or severe disease as acute pancreatitis creates a catabolic state that promotes nutritional depletion. This can impair recovery, increase the risk of complications, and prolong hospitalization.[38] Enteral nutrition results in decreased multiple organ failure, complications, duration of hospitalization, mortality, and need for surgical intervention compared with parenteral nutrition.[38,39] Possible mechanisms for this include protection of the gut barrier and prevention of colonization with pathogenic bacteria, both of which may prevent translocation of bacteria and subsequent infection.[3,4] Patients with mild to moderate acute pancreatitis should begin oral feeding as soon as clinically tolerated regardless of serum lipase concentrations, usually within 24 hours of admission.[1,38] In severe or complicated disease, nutritional deficits develop rapidly and are complicated by tissue necrosis, organ failure, and surgery. Despite this guideline, recommendations support beginning oral or enteral nutrition within 24 to 72 hours of admission.[38,40] If the enteral route is used due to intolerance of an oral diet, based on guidelines make preference for nasogastric feeding tube placement over nasojejunal.[1,38,41] If enteral feeding is not possible or if the patient is unable to obtain sufficient nutrients, total parenteral nutrition should be implemented before protein and calorie depletion become advanced.[1,2,38]

Probiotics have mixed results in several randomized controlled trials for the treatment of severe acute pancreatitis. A meta-analysis, however, did not support the use of probiotics in the treatment of acute pancreatitis, as they have no a benefit.[42] Therefore, use of probiotic agents for acute pancreatitis is not recommended by guidelines.[38]

Pharmacologic Therapy

Patients with acute pancreatitis often require IV antiemetics for nausea. Those requiring ICU admission should be treated with antisecretory agents (such as famotidine or pantoprazole) if they are at risk of stress-related mucosal bleeding. Patients also require appropriate fluid resuscitation and pain management, but there is controversy surrounding both of these therapies (see Fig. 57-3). Clinical trials have also failed to identify a group of patients that benefit from prophylactic antibiotics.

Fluid Resuscitation

② Vasodilation from the inflammatory response, vomiting, and nasogastric suction contributes to hypovolemia and fluid and electrolyte abnormalities, thus necessitating replacement. Patients with acute pancreatitis should receive goal-directed fluid management to reduce the risks of persistent SIRS and organ failure.[1] Recommendations regarding the volume of fluid differ, with anywhere from 250 to 500 mL/hr to 5 to 10 mL/kg/hr in the first 12 to 24 hours.[3,4,13] Goals for fluid therapy in the management of acute pancreatitis are not well-defined but include one or more of the following: heart rate less than 120/min, mean arterial pressure 65 to 85 mm Hg, urinary output greater than 0.5 to 1 mL/kg/hr, or hematocrit 35% to 44% (0.35-0.44) with transfusion of blood.[3,4]

Studies completed to date have been of low quality and have somewhat conflicting results. Observational studies have identified both benefit (decreased mortality and markers of organ failure) and harm (abdominal compartment syndrome) associated with early aggressive fluid administration.[1,2] Mortality was lower in patients with severe acute pancreatitis who received 6 L or more of resuscitation fluid in the first 24 hours.[43] In contrast, there is no benefit to mortality and a greater risk of acute kidney injury and acute respiratory failure in patients who received aggressive fluid therapy.[44] Patients with sepsis should be resuscitated according to sepsis guidelines.[45]

In addition to questions about the rate and volume of fluid that should be administered to patients with acute pancreatitis, there is also debate regarding which fluid is most appropriate. There is no difference in mortality between saline and lactated Ringer's, but did find a lower odds of SIRS at 24 hours with lactated Ringer's.[46] Lactated Ringer's was associated with a shorter length of hospitalization.[47] Guidelines differ regarding which fluid is preferred with most recommending lactated Ringer's in adult patients.[4] The American Gastroenterological Association Institute Guideline on Initial Management of Acute Pancreatitis also recommends against the use of hydroxyethyl starch solutions because there are no benefits beyond saline and lactated Ringer's, and an association with an increase in multiple organ failure.[1]

Relief of Abdominal Pain

③ Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis despite a lack of high-quality evidence to support the practice. Pentazocine led to lower rescue analgesic use and a longer pain-free period compared to parenteral diclofenac.[48]

NSAIDs, however, may be sufficient in patients with mild or moderate pain due to acute pancreatitis and can be used if not otherwise contraindicated.[49] Parenteral morphine is often recommended for pain control because it provides a longer duration of pain relief than other opioids. Although morphine increases biliary pressure, it is contraindicated for use in acute pancreatitis. Patient-controlled analgesia should be considered in patients who require frequent opioid dosing (eg, every 2-3 hours). There was a reduction in 30-day mortality in patients with acute pancreatitis who received thoracic epidural analgesia compared to those who received a standard approach to pain management.[50]

Antimicrobial Use in Acute Pancreatitis

④ Use of prophylactic antibiotics is not recommended in patients with acute pancreatitis without signs or symptoms of infection, including those predicted to develop acute pancreatitis or necrotizing pancreatitis.[1,2] Several small, randomized clinical trials have compared antibiotic prophylaxis with no prophylaxis in patients with severe acute and necrotizing pancreatitis with varying results. Prophylactic antibiotics do not reduce infected necrosis or mortality.[2,51] In addition, overuse of antibiotics increases microbial resistance.

Because the source of bacterial contamination is most likely translocation of organisms from the colon, the antibiotic regimen for patients with known or suspected infected pancreatitis should be broad-spectrum, covering the range of enteric aerobic gram-negative bacilli and anaerobic microorganisms. Imipenem–cilastatin (500 mg IV every 8 hours) has been widely used because of its good penetration into the pancreas and one positive prophylaxis study.[52] However, it has been replaced on many hospital formularies by one of the newer carbapenems (eg, meropenem). Fluoroquinolones, such as ciprofloxacin or levofloxacin, combined with metronidazole should be considered for penicillin-allergic patients.[53] Patients with infected necrotic pancreatitis are generally treated with a combination of invasive interventions and antibiotics. Antibiotics alone may be sufficient in some cases or at least delay the need for an invasive procedure long enough for the necrotic areas to be walled off.[3]

Post-ERCP Pancreatitis

The clinical characteristics of post-ERCP pancreatitis are similar to those of acute pancreatitis from other causes. In most cases, the disease course is mild and resolves in several days. The incidence of post-ERCP pancreatitis has decreased in recent decades, most likely due to better patient selection. Several classes of medications have been studied for prevention of post-ERCP pancreatitis. The best data are with nonsteroidal anti-inflammatory drugs (NSAIDs) administered rectally prior to or immediately following the procedure.[54] The most common beneficial NSAIDs are indomethacin and diclofenac. The combination of rectal diclofenac and sublingual isosorbide dinitrate was superior to diclofenac alone in prevention of post-ERCP pancreatitis, but this finding needs to be validated in additional studies.[55] Another agent that reduced post-ERCP pancreatitis is gabexate mesilate; however, this agent is not approved in the United States.[56] In addition to NSAIDs more aggressive peri-procedural hydration with intravenous crystalloids reduces the occurrence of post-ERCP pancreatitis.[57,58]

CHRONIC PANCREATITIS

Chronic pancreatitis results from long-standing pancreatic inflammation resulting in irreversible destruction of pancreatic tissue with fibrin deposition, leading to a loss of exocrine and endocrine functions.[5–11] It has four different stages beginning with a preclinical inflammatory stage where patients remain asymptomatic or have indistinguishable symptoms.[9] In the second-stage patients present with acute attacks that often resemble those of acute pancreatitis. The third stage consists of episodes of intermittent or constant abdominal pain. Finally, in the burnout stage patients present with diminished or absent pain, but develop malabsorption syndrome due to loss of pancreatic exocrine function and may develop diabetes mellitus from loss of endocrine function.

Etiology

Chronic alcohol consumption remains the leading cause of chronic pancreatitis in Western society, accounting for up to two-thirds of cases.[10,11,59,60] The consumption of 40 g/day or more of alcohol poses a significant risk of chronic pancreatitis.[60] Most of the remaining cases can be classified as idiopathic, while a small percentage of cases are due to rare causes, such as autoimmune, hereditary, and tropical pancreatitis.[10,11,61] Various genetic alterations have also been associated with the occurrence of chronic pancreatitis, including mutations of the following genes: protease serine 1 (trypsin 1) (*PRSS1*), serine peptidase inhibitor Kazal type 1 (*SPINK1*), cystic fibrosis transmembrane conductance regulator (*CFTR*), chymotrypsin C, chymotrypsin B1/B2, carboxypeptidase A1, and carboxyl ester lipase (CEL).[8,10,11,59,62,63] There is also a risk of chronic pancreatitis with cigarette smoking that appears to be dose-dependent and may contribute to mortality from chronic pancreatitis.[8,11,15,59,61,64] There are two classification systems for chronic pancreatitis that take into account the various risk factors associated with the disease (Table 57-4).[59]

TABLE 57-4

Classification of Etiology and Risk Factors for Chronic Pancreatitis

M-ANNHEIM	
Multiple	Risk factors
Alcohol	Excessive consumption (>80 g/day), increased consumption (20-80 g/day), moderate consumption (<20 g/day)
Nicotine	Quantitated in pack-years for current smokers
Nutritional factors	High-fat and protein diet, hyperlipidemia (especially hypertriglyceridemia)
Hereditary factors	Hereditary pancreatitis, familial pancreatitis, early and late-onset idiopathic pancreatitis, tropical pancreatitis, possible gene mutations (eg, *PRSS1*, *SPINK1*, and *CFTR*)
Efferent duct factors	Pancreas divisum, annular pancreas/congenital abnormalities, pancreatic duct obstruction (eg, tumors), posttraumatic pancreatic duct scars, sphincter of Oddi dysfunction
Immunologic factors	Autoimmune pancreatitis
Miscellaneous and rare factors	Hypercalcemia and hyperparathyroidism, chronic kidney disease, medications, toxins
TIGAR-O	
Toxic-metabolic	Alcohol, tobacco smoking, hypercalcemia, hyperlipidemia, chronic kidney disease, medications, toxins
Idiopathic	Early onset, late-onset, tropical pancreatitis
Genetic mutations	*PRSS1, CFTR, SPINK1*, others
Autoimmune	Isolated, syndromic
Recurrent and severe associated acute pancreatitis	Postnecrotic (severe acute pancreatitis), vascular disease/ischemic, postirradiation
Obstructive	Pancreas divisum, sphincter of Oddi dysfunction, pancreatic duct obstruction (eg, tumor), posttraumatic pancreatic duct scars

Pathophysiology

Although the exact mechanism for the pathogenesis of chronic pancreatitis is unknown, several theories have been proposed. One of the main theories is that repeated episodes of acute pancreatitis lead to the occurrence of chronic pancreatitis.[10,11,59,65] Repeated episodes of acute pancreatitis initiate inflammation and necrosis that leads to ductal scarring and fibrosis. This leads to ductal obstruction and eventually results in acinar atrophy and fibrin deposition.

Regardless of the pathophysiologic mechanism, activation of pancreatic stellate cells is the cause of fibrin deposition in chronic pancreatitis. Various toxins, oxidative stress, and inflammatory mediators activate pancreatic stellate cells.[10,11,61,65] Activated pancreatic stellate cells then initiate fibrinogenesis. Other mediators generated by the stellate cells themselves perpetuate continued stellate cell activation.

The pathogenesis of pain in chronic pancreatitis has long been thought to be the result of increased pancreatic parenchymal pressure from obstruction, inflammation, and necrosis.[10] However, there is a neurogenic origin of pain. There is abnormal pain processing in the central nervous system of patients with chronic pancreatitis, with functional reorganization of the insular cortex.[10,61] Also, visceral nerves in these patients are sensitized. This may explain the hyperalgesia often experienced by these patients, and the need for various methods of pain management.[11] Patients with chronic pancreatitis may also experience pain in areas distant to the pancreas due to impaired inhibition of somatic and visceral pain pathways.

⑤ Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark symptoms and complications of chronic pancreatitis. Although abdominal pain is the most common symptom at any stage, patients may present with various signs and symptoms depending on the stage of the disease. A more comprehensive list of the common signs and symptoms is presented in Table 57-5.

TABLE 57-5

Signs, Symptoms, and Diagnosis of Chronic Pancreatitis

Signs

- Malnutrition (especially in chronic alcohol misuse)
- Abdominal mass (may indicate a pancreatic pseudocyst)
- Jaundice may be seen
- Splenomegaly (rare)

Symptoms

- Abdominal pain
    - Commonly in epigastric area
    - May radiate to the back
    - Described as deep and penetrating
    - May be relieved by bending/leaning forward or bringing knees to the chest
    - Often occurs with meals and at night
    - May be associated with nausea and vomiting
- Steatorrhea
    - Patients describe bulky or foul-smelling stools often with obvious oil droplets
    - Usually have an average of three to four stools per day
    - May be associated with deficiencies in fat-soluble vitamins
    - Watery diarrhea, excess gas, and abdominal cramps are uncommon
- Pancreatic diabetes mellitus
- Diarrhea (associated with steatorrhea)
- Weight loss
    - May be due to severe malabsorption or acute/chronic pain
    - Substantial loss may be due to associated or unrelated malignancy
- Osteopenia/Osteoporosis (from vitamin D malabsorption and increased bone resorption)

- Bone fractures
- Dyspepsia

Laboratory studies

- CBC to rule out infection (ie, infected pseudocyst)
- Serum amylase and lipase
  - Low specificity for chronic pancreatitis
  - May be elevated in acute exacerbations
  - Usually are normal or only slightly elevated
- Total bilirubin, alkaline phosphatase, and hepatic transaminases may be elevated with ductal obstruction
- Fasting serum glucose or hemoglobin A_{1c}
- Screening for fat-soluble vitamin (ie, A, D, E and K) and mineral (ie, magnesium, iron, selenium, and zinc) deficiency
- Pancreatic function tests
  - Indirect
    Serum trypsinogen (<20 ng/mL [mcg/L] is abnormal)
    Fecal elastase (<200 mcg/g of stool is abnormal)
    Fecal chymotrypsin (<3 units/g of stool is abnormal)
    Fecal fat estimation (>7 g/day is abnormal; need to collect 72 hours of stool)
    ^{13}C-mixed triglyceride breath test (conducted over 6 hours; not available in the United States)
  - Direct
    Secretin stimulation (evaluates duodenal bicarbonate secretion)
    Cholecystokinin stimulation (evaluates pancreatic lipase secretion)
  - Serum albumin (may be low with malnutrition)
  - Serum calcium (may be low with malnutrition)

Imaging studies

- Noninvasive
  - Abdominal ultrasound
  - Computed tomography (CT)
  - Magnetic resonance imaging (MRI)
  - Secretin-enhanced magnetic resonance cholangiopancreatography
- Invasive
  - Endoscopic ultrasonography (EUS)
  - Endoscopic retrograde cholangiopancreatography (ERCP)
- Dual-energy X-ray absorptiometry to assess for osteopenia and osteoporosis

CBC, complete blood count.

Data from References 8–11,23,38,63,66, 67,79.

Diagnosis

The diagnosis of chronic pancreatitis is based primarily on presenting signs and symptoms in combination with either imaging, pancreatic function studies, or histological examination (see Table 57-5). Although histology would be the best diagnostic test, it is recommended only in high-risk patients with strong clinical and functional evidence, but inconclusive imaging studies.[61,63] Therefore, testing usually begins with noninvasive or invasive imaging studies. Abdominal ultrasonography, computed tomography (CT), and magnetic resonance imaging may be used first, but are limited in their ability to produce detailed imaging of pancreatic ductal abnormalities.[8,11,63,68] Invasive studies, such as endoscopic ultrasonography (EUS), are recommended when noninvasive studies are inconclusive.[8,11,63] Secretin-enhanced magnetic resonance cholangiopancreatography produces more detailed images of the pancreatic ducts, and is recommended if all other imaging studies cannot confirm a diagnosis and clinical suspicion remains high.[8,11,59,63,68,69] While ERCP is the gold standard invasive study, it is rarely used due to inter- and intra-observer variability, the risk of post-ERCP pancreatitis, and lack of high-quality evidence comparing it to other imaging studies such as CT, MRI, and EUS.[59,63,68,69] In addition to imagining studies, pancreatic function tests are used when imagining is inconclusive, as adjunctive diagnostic studies or to quantify the degree of exocrine insufficiency.[63,68] The most sensitive studies are the secretin and CCK stimulation tests.[59,68,69] However, these are not widely available and are uncomfortable for patients. Indirect studies of pancreatic function are most sensitive during late chronic pancreatitis.[59]

Clinical Course and Prognosis

The clinical course of chronic pancreatitis depends on the etiology. Exocrine insufficiency occurs when lipase secretion is less than 10% of normal.[9,63,69] Patients with hereditary chronic pancreatitis typically have exocrine insufficiency occur at an early age, while those with alcohol-induced disease have exocrine insufficiency occur about 5 years after disease onset, with “burnout” of the pancreas in about 10 to 20 years.[69,70] Patients with early-onset idiopathic chronic pancreatitis have delayed progression to exocrine insufficiency compared to those with alcohol-induced or late-onset idiopathic disease.[66] Diabetes mellitus occurs later than exocrine insufficiency and has a reported prevalence of 25% to 80%.[8,71]

The median survival of patients with chronic pancreatitis is estimated to be 15 to 20 years after diagnosis.[11] One of the most significant complications of long-standing disease is pancreatic cancer. Patients with chronic pancreatitis have a 16-fold increased risk of pancreatic cancer.[72] This risk increases depending on the etiology, with patients who smoke having twice the risk.[69]

Treatment

Desired Outcome

The major goals in the treatment of uncomplicated chronic pancreatitis are relief of abdominal pain, treatment of any associated complications such as malabsorption and diabetes mellitus, and improvement in quality of life. Secondary goals include delaying development of complications and treating associated disorders such as depression and malnutrition.

General Approach to Treatment

Treatment of chronic pancreatitis and its complications involves various nonpharmacologic and pharmacologic interventions. Lifestyle modifications should include abstinence from alcohol and smoking cessation.[8,11,63,68,69] In addition, patients with steatorrhea may need to eat smaller, more frequent meals and reduce dietary fat intake.[9,38,63,69] The majority of patients require analgesics and pancreatic enzyme replacement therapy (PERT).[8,11,38,63,68,69] Pain can initially be controlled with medications, but may require more aggressive medical and surgical therapies as the disease progresses. Patients with malabsorption require pancreatic enzymes to reduce steatorrhea and maintain adequate nutrient absorption.[8,11,38,63,68,69] An antisecretory agent may be added to the regimen when enzymes alone provide an inadequate reduction in steatorrhea.[8–10,38,63,69]

Nonpharmacologic Therapy

In addition to medical management, the treatment of chronic pancreatitis includes both lifestyle and dietary modifications. Patients should be counseled to abstain from alcohol use, and smoking cessation should be advocated. Cessation of alcohol use may reduce pain in patients with alcohol-induced chronic pancreatitis, and hastens disease progression and reduces the risk of developing pancreatic cancer.[8,9,11,63,68,69] Smoking has been associated with pain relapses and progression of disease, so cessation should be advocated.[8,11,63] Patients with steatorrhea should be counseled to eat small and frequent meals.[38,63,69] A reduction in dietary fat is not needed routinely, but may be needed in those whose symptoms are uncontrolled with enzyme PERT.[38,68,73] Enteral nutrition via a feeding tube is recommended for patients with malnutrition who do not have an adequate response to oral nutrition support.[38] For patients with chronic pancreatitis requiring tube feeding, use of a jejunal feeding tube is recommended.[38,66]

Invasive procedures and surgery are primarily used to treat uncontrolled pain and the associated complications of chronic pancreatitis. Stents placed via ERCP may be used to treat pancreatic duct strictures in order to relieve parenchymal pressure and reduce pain.[8,63,68,74] Extracorporeal shock wave lithotripsy can be used to break up pancreatic stones with ultrasonic vibration prior to removal by ERCP.[8,11,74,75] Blockade of pain signals through the celiac plexus may be achieved utilizing EUS.[11,63,68,74] The various complications of chronic pancreatitis that can be treated endoscopically include common bile duct strictures, duodenal obstructions, and pancreatic pseudocysts.[8,11,63,68,74] Various surgical techniques including total pancreatectomy may also be used to relieve pain associated with chronic pancreatitis.[23,67,76] Surgery is more effective at relieving pain than endoscopic procedures, but is usually reserved when endoscopic therapy fails.[8,11,63,68,76,77] Finally, total pancreatectomy with transplantation of pancreatic islet cells to reduce the need for exogenous insulin is recommended as a last-line option for the treatment of pain due to chronic pancreatitis.[8,11,63,68]

Pharmacologic Therapy

General Recommendations

Pharmacologic therapy of chronic pancreatitis is aimed at controlling pain, treating malabsorption and associated steatorrhea, and controlling diabetes mellitus. Once other causes have been excluded, acetaminophen with or without NSAIDs should be tried initially for pain management (Fig. 57-4).[8,11,61,65,66] Patients with inadequate relief from these agents should have adjuvant agents added to their regimen, with opioid analgesics reserved for patients with refractory pain.[8,11,65,66,68,69] The addition of pancreatic enzyme supplements for pain control has been studied, but is not recommended based on available evidence.[8,9,11,61,63,65,68,69] Antioxidants are recommended for relief of pain due to chronic pancreatitis based on some trials.[8,11,63]

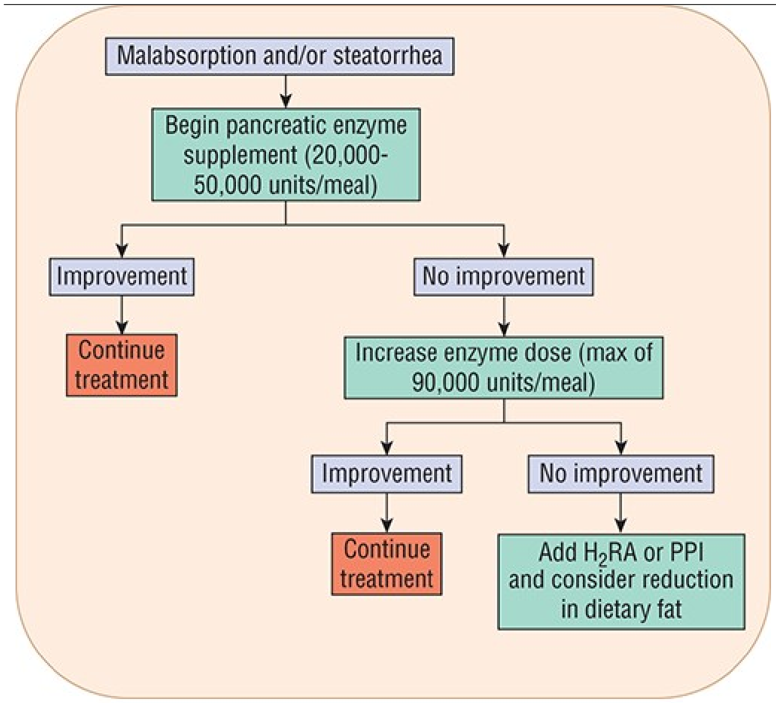
Most patients with malabsorption will require pancreatic enzyme supplementation in order to achieve adequate nutritional status and reduction in steatorrhea (Fig. 57-5). An antisecretory agent (ie, histamine-2 receptor antagonist or proton pump inhibitor) should be added to the regimen when there is an inadequate response to enzyme therapy alone.[8,38,63,68,69,73] If these measures are ineffective, documentation of the diagnosis and exclusion of other diseases should be undertaken. Exogenous insulin is the primary pharmacologic agent used in the treatment of diabetes mellitus associated with chronic pancreatitis.[8,9,61,65] Metformin may be initiated in early chronic pancreatitis, and has the added benefit of significantly reducing the risk of pancreatic cancer.[8,61,65]

FIGURE 57-5

Algorithm for the treatment of malabsorption and steatorrhea in chronic pancreatitis. (H_2RA, histamine-2 receptor antagonist; PPI, proton pump inhibitor)



Malabsorption and/or steatorrhea
Begin pancreatic enzyme supplement (20,000-50,000 units/meal)
Improvement
No improvement
Continue treatment
Increase enzyme dose (max of 90,000 units/meal)
Improvement
No improvement
Continue treatment
Add H2RA or PPI and consider reduction in dietary fat

Relief of Chronic Abdominal Pain

Analgesics

⑥ Pain from chronic pancreatitis may initially be treated with nonopioid analgesics, but adjuvant agents may be necessary as the disease progresses. Regimens should be individualized and should begin with the lowest effective dose. The dosage regimen should be maximized before adding or substituting agents. Analgesics should be scheduled around the clock rather than as needed in order to maximize efficacy. Scheduling short-acting analgesics prior to meals should help decrease postprandial pain. Following the World Health Organization pain ladder, acetaminophen or NSAIDs should be used initially.[8,11,61,65–67] As the response diminishes to adequate doses of nonopioid analgesics, adjuvant agents should be added to the regimen.[8,11,61,65,67] Tramadol may also be effective and could be tried before adding opioid analgesics.[11,67] Opioids are used last as other agents become ineffective or patients have intolerance (Table 57-6).[8,11,61,63,65,66,73]

TABLE 57-6

Recommendations for the Pharmacologic Treatment of Chronic Pancreatitis

Treatment of chronic pain (oral drug regimens)

Nonopioid analgesics

- Begin with acetaminophen at doses of 500-650 mg per dose every 4-6 hours following product labeling for maximum daily dose; caution for patients also receiving acetaminophen from other combination analgesics, and in those with liver disease
- Can also start with NSAIDs at low doses (ie, 200-400 mg ibuprofen every 6-8 hours) and titrate to maximum recommended doses as needed; caution in patients with cardiovascular disease or high disease risk, and in patients with kidney impairment or disease

Adjuvant agents

- Pregabalin has the best evidence; begin with 75 mg twice daily; maximum dose of 300 mg twice daily
- Consider use of selective serotonin reuptake inhibitors (eg, paroxetine), serotonin/norepinephrine reuptake inhibitors (eg, duloxetine) and tricyclic antidepressants in patients with difficult-to-manage pain

Opioids

- Tramadol: 50-100 mg every 4-6 hours, not to exceed 400 mg/day; has opioid-like effect; contraindicated in alcohol or hypnotic intoxication; be aware of drug interactions; expensive
- Codeine 30-60 mg every 6 hours; hydrocodone 5-10 mg every 4-6 hours; morphine sulfate (extended-release) 30-60 mg every 8-12 hours; oxycodone 5-10 mg every 6 hours; methadone 2.5-10 mg every 8-12 hours; hydromorphone 0.5-1 mg every 4-6 hours; fentanyl patch 25-100 mcg/hr every 72 hours
- Risk of potentiation with alcohol; impaired respiration; constipation; hypotension; allergy
- Dosing is usually based on providing continuous pain relief; consider combining with acetaminophen; opioid dependence is common; abuse is a concern in patients who misuse alcohol; tolerance may develop

Treatment of malabsorption and steatorrhea

- Start with pancreatic enzymes containing 20,000-50,000 USP units of lipase with each meal of a preferred product (see Table 57-7); administer dose during meals; administer multiple capsules/tablets throughout the meal; use half the mealtime dose with snacks
- Increase dose to a maximum of 90,000 USP units of lipase per meal
- Products containing enteric-coated microspheres may be more effective than other dose forms

Acid-suppression agents

- May improve efficacy of enzyme therapy for malabsorption and steatorrhea
- Preferred for use with nonenteric-coated dose forms

USP, United States Pharmacopeia.

Pancreatic Enzymes

Although pancreatic enzymes are primarily used to treat malabsorption associated with chronic pancreatitis, they have also been used to treat pain from the disease. Relief of pain using pancreatic enzymes is thought to be due to their ability to break down CCK.[9,66,68] Release of CCK is normally inhibited by trypsin, but patients with chronic pancreatitis have decreased trypsin production. The proteases in pancreatic enzyme supplements are thought to act as substitutes for endogenous trypsin, leading to a decrease in CCK release. However, there are mixed results from trials investigating pancreatic enzyme supplements for the treatment of pain from chronic pancreatitis. This may be due to the differences between the various enzyme formulations used in the trials as well as the small number of subjects enrolled.[9,11,63,68,69] However, trials that used nonenteric-coated enzyme formulations have a benefit in the treatment of pain.[65,66,79] Enteric-coated formulations may not release enough proteases in the duodenum to inhibit

CCK release. Despite their intuitive mechanism current guidelines do not recommend the use of pancreatic enzyme therapy for the treatment of pain from chronic pancreatitis due to lack of beneficial outcomes.[63,73]

Other Agents

Various adjuvant agents are also used in patients experiencing pain from chronic pancreatitis. Selective serotonin reuptake inhibitors and tricyclic antidepressants are used both for treating the concomitant depression that often occurs in patients with chronic pancreatitis and for their potential effects on pain (see Table 57-6).[8,9,11,61,65] Gabapentin and pregabalin are effective adjunct analgesics.[8,9,11,61,80] Patients with chronic pancreatitis have increased oxidative stress, and the use of antioxidants, such as selenium, vitamins C and E, and β-carotene, has some benefit in relieving pain and improving quality of life in these patients.[11,63,81–83] The details of their benefit remains variable, but due to their low cost and relative safety, the American College of Gastroenterology guidelines for chronic pancreatitis considers their use for treatment of pain.[63]

Treatment of Malabsorption

⑦ Pancreatic enzyme and fat-soluble vitamin supplementation are the primary treatments for malabsorption due to chronic pancreatitis. Treatment should begin when steatorrhea is documented and persistent weight loss occurs despite any dietary modifications. The utilization of pancreatic enzymes enhances the patient's nutritional status and reduces steatorrhea and resultant abdominal symptoms. Malabsorption is minimized if the concentration of lipase delivered to the duodenum with supplementation is about 10% of normal pancreatic output.[9] This requires that 250000 to 50,000 units of lipase be administered with each meal to start (see Table 57-6).[38,61,68,73,78,84] Half of the necessary mealtime dose is recommended with snacks.[38,73,78] In many cases the lipase dose will need to be increased due to insufficient lipolytic activity, but doses greater than 90,000 units per meal are not recommended. In addition to enzyme replacement therapy, patients with chronic pancreatitis have deficiencies in fat-soluble vitamins.[38,63,85] Thus, they should be assessed for vitamin deficiencies and provided necessary supplementation as required.[9,38,63,69,73,78]

⑧ There is little evidence regarding the optimal dosage form and administration of pancreatic enzyme supplements. Most studies have compared them with placebo rather than other enzyme products, and used quantitation of fat absorption or elimination as a primary measure of efficacy rather than weight gain.[63,86] While they may not completely eliminate steatorrhea, they improve nutritional parameters and quality of life of patients with chronic pancreatitis.[8,11,63,69] Since most exogenous lipase is rapidly and irreversibly destroyed at low intragastric pH, enteric-coated products are preferred for the treatment of malabsorption and steatorrhea. The enteric coating only dissolves at a pH greater than 5.5, which allows a sufficient quantity of enzymes to remain intact until dissolution of the coating in the duodenum.[38,69] However, enzymes must also be emptied from the stomach into the duodenum at the same rate and time as ingested food. The size of the enteric-coated enzyme preparation influences the rate of enzyme delivery to the duodenum.[9] Likewise, the administration time relevant to a meal influences the timing of enzyme delivery. Products containing enzymes in small enteric-coated microspheres are preferred, and they should be administered with meals.[38,61,69,73,84] Ideally, patients should eat five to six small meals per day, and if patients need to take more than one capsule/tablet per meal the doses should be distributed throughout the meal.[38,61,73]

Despite enzyme therapy, patients may continue to have steatorrhea and fail to have improvement in nutritional parameters. Adherence should be assessed in these patients as the number of capsules required with each meal can lead to reduced adherence. Alternative products with higher lipase content can be tried in order to reduce the number of capsules needed. If this fails, the dose of lipase should be increased. Finally, addition of an antisecretory agent (ie, histamine-2 receptor antagonist or proton pump inhibitor) may be tried to increase the availability of active enzymes in the duodenum.[8,38,69,73,78,84]

Pancreatic Enzyme Supplements

Five pancreatic enzyme products are approved by the FDA, but only two of these products are specifically approved for exocrine pancreatic insufficiency associated with chronic pancreatitis.[87,88] Dosage forms of approved products include regular-release tablets, enteric-coated beads, bicarbonate-buffered enteric-coated microspheres, enteric-coated microspheres, and enteric-coated minitablets or microtablets encased in a cellulose or gelatin capsule (Table 57-7). Enzymes are easily administered to patients who are able to swallow the capsules or their contents. However, administration to patients with enteral feeding tubes presents a challenge. Products containing microspheres may be administered through feeding tubes in food or solutions with a pH of 4.5 or less.[38,84] Clinicians must be aware, however, that available products are not equivalent and should consider this before substituting products in patients who require administration through a nonoral route. Careful consideration should also be given to this issue in patient care facilities with limited formularies.

TABLE 57-7

Commercially Available Pancreatic Enzyme (Pancrelipase) Preparations

	Enzyme Content Per Unit Dose (USP Units)		
Product	**Lipase**	**Amylase**	**Protease**
Tablets			
ViokaceTM 10,440 lipase units	10,440	39,150	39,150
ViokaceTM 20,880 lipase units	20,880	78,300	78,300
Enteric-coated beads			
Zenpep® 3,000 lipase units	3,000	14,000	10,000
Zenpep® 5,000 lipase units	5,000	24,000	17,000
Zenpep® 10,000 lipase units	10,000	42,000	24,000
Zenpep® 15,000 lipase units	15,000	63,000	47,000
Zenpep® 20,000 lipase units	20,000	84,000	63,000
Zenpep® 25,000 lipase units	25,000	105,000	79,000
Zenpep® 40,000 lipase units	40,000	168,000	126,000
Enteric-coated microspheres with bicarbonate buffer			
Pertzye 4,000 lipase units	4,000	15,125	14,375
Pertzye 8,000 lipase units	8,000	30,250	28,750
Pertzye 16,000 lipase units	16,000	60,500	57,500

USP, United States Pharmacopeia.

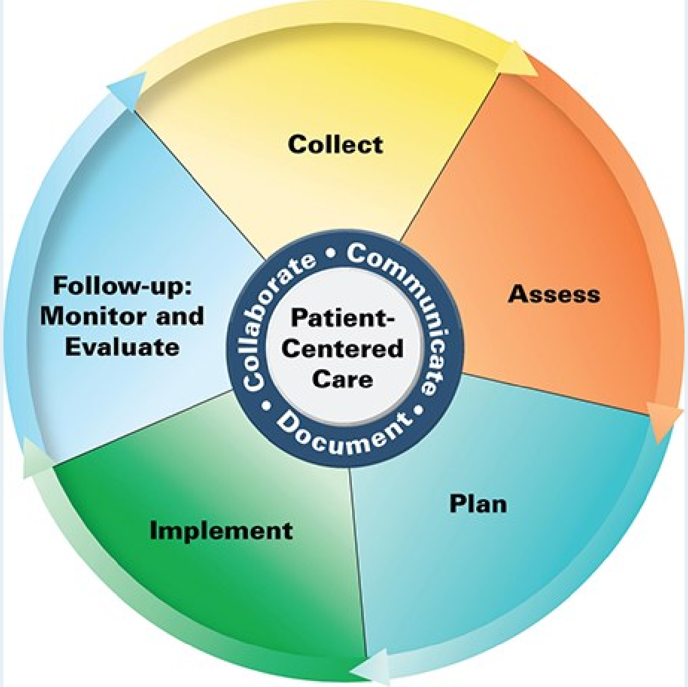
Adverse reactions from pancreatic enzyme supplements are generally benign. High doses can lead to nausea, diarrhea, and intestinal upset.[69] One of the more serious adverse effects of these products is fibrosing colonopathy. It occurs when the enzymes cause deposition of fibrin in the colon leading to colonic stricture. This reaction is uncommon and has been reported mostly in children with cystic fibrosis who received high doses of enzymes for prolonged periods.[38,69] Another concern with pancreatic enzymes is the risk of possible viral infection due to contamination of these porcine-derived products.[69]

Adjuncts to Enzyme Therapy

⑨ The addition of a histamine-2 receptor antagonist or proton pump inhibitor to pancreatic enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and steatorrhea. The beneficial effects of these agents result from an increase in gastric and duodenal pH.[38,69,84] This results in an increase in the amount of active enzymes available in the duodenum. Their use has been mainly recommended with nonenteric-coated enzyme products.[9,68,73,78] In fact, the only nonenteric-coated formulation approved by the FDA is indicated for administration with a proton pump inhibitor.[88]

PATIENT CARE PROCESS

Patient Care Process for Pancreatitis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient history (past medical—hyperlipidemia, recent surgery, gallstone disease or ERCP; social—dietary habits, alcohol use, tobacco use)
- Current and recent (for acute pancreatitis; see Table 57-2) medications
- Medication allergies
- Review of systems for the abdomen and gastrointestinal system (eg, abdominal pain, nausea and vomiting, stool frequency and consistency for chronic pancreatitis; see Table 57-3 and 57-5)
- Objective data
    - Acute pancreatitis (see Table 57-3)
        - Vital signs (eg, BP, heart rate, temperature, respiratory rate)
        - Labs (eg, CBC, Chem-7, calcium, albumin, amylase, lipase, transaminases, bilirubin, triglycerides)
        - Microbiology results
        - Intake/output
    - Chronic Pancreatitis (see Table 57-5)
        - Physical exam (eg, weight; assessment for neuropathy, nephropathy, and retinopathy with diabetes)
        - Labs (eg, fasting serum glucose, bilirubin, transaminases, pancreatic function tests, fat-soluble vitamins, zinc, magnesium, calcium, albumin)

Assess

- Acute pancreatitis
    - Causative medications (see Table 57-2)
    - Nutrition and fluid status
    - Abdominal pain: location, radiation, severity, onset
    - Infectious etiologies
    - Continuous hemodynamic monitoring
- Chronic pancreatitis
    - Alcohol and tobacco use
    - Abdominal pain
    - Trends in weight, nutrition status, serum glucose, and stool consistency and frequency (assess for constipation if patient is taking opioids)

Plan*

- Acute pancreatitis
    - Fluid support including choice and dose
    - Discontinue suspected causal medications
    - Nutrition support including route and caloric requirements
    - Pain management with specific medication choice, route, and dose
    - Antimicrobial therapy regimen for suspected or identified infection(s)
- Chronic pancreatitis
    - Tailored lifestyle modifications (eg, abstinence from alcohol, smoking cessation; see Fig. 57-4)
    - Nutrition support and dietetic counseling
    - Therapy for abdominal pain (see Fig. 57-4) with analgesics (see Table 57-6) and pancreatic enzymes (see Table 57-7), including the need for treatment of constipation if opioids are utilized
    - Therapy for malabsorption (see Fig. 57-5, and Tables 57-6 and 57-7)
    - Treatment of concomitant diabetes mellitus if present

Implement

- Consultation with additional providers as necessary (eg, dietician, pain management specialist, infectious diseases, gastroenterology, endocrinology) and consider transfer to a specialty center if severe disease
- Pain therapy with clearly identified goals for both the provider and patient
- Fluid and nutrition support as appropriate
- Necessary lifestyle modifications (eg, alcohol and smoking cessation)

- For patients with acute pancreatitis consider antimicrobial therapy if suspected or known infection and narrow coverage based on cultures and sensitivities
- For patients with malabsorption due to chronic pancreatitis initiate appropriate pancreatic enzyme therapy

Follow-Up: Monitor and Evaluate

- Pain control and constipation if opioids utilized
- Acute pancreatitis
  - Fluid and electrolytes along with kidney and liver function (eg, serum creatinine, BUN, bilirubin, transaminases)
  - Signs and symptoms of infection along with microbiology culture and sensitivity results
  - Hemodynamic parameters for signs of decreased intravascular volume and shock
  - Nutrition status and support (eg, prealbumin, albumin, changes in caloric requirements and delivery route)
  - Discontinuation of causative medication(s) on discharge and identification of necessary therapeutic alternative(s)
  - Brief alcohol cessation intervention prior to discharge for alcohol-related acute pancreatitis
- Chronic pancreatitis
  - Alcohol intake and smoking status utilizing motivational interviewing
  - Weight and effects of diet on abdominal pain and malabsorption symptoms
  - Efficacy of pancreatic enzymes on symptoms of malabsorption (see Fig. 57-5)
  - Serum blood glucose along with signs and symptoms of diabetes mellitus

***Collaborate with patients, caregivers, and other healthcare professionals.*

EVALUATION OF THERAPEUTIC OUTCOMES

Acute Pancreatitis

Hydration status, serum electrolytes, pain control, and nutritional status should be assessed periodically in patients with mild acute pancreatitis, depending on the degree of abdominal pain and fluid loss. Patients with severe acute pancreatitis should receive intensive care and close monitoring of vital signs, fluid and electrolyte status, white blood cell count, blood glucose, lactate dehydrogenase, aspartate aminotransferase, serum albumin, hematocrit, BUN, serum creatinine, and international normalized ratio. Continuous hemodynamic and arterial blood gas monitoring is essential. Serum lipase, amylase, and bilirubin require less frequent monitoring. The patient should also be monitored for signs of infection, relief of abdominal pain, and adequate nutritional status. Severity of disease and patient response should be assessed using an evidence-based method.

Chronic Pancreatitis

The severity and frequency of abdominal pain should be assessed periodically in patients with chronic pancreatitis using a standardized scale in order to determine the efficacy of pain therapy. Patients receiving opioids should be prescribed laxatives on an as-needed or scheduled basis and be monitored for constipation. Patients receiving pancreatic enzymes for malabsorption should have their weight and stool frequency and consistency monitored periodically. More objective assessments of fecal fat content, such as the ^{13}C-mixed triglyceride breath test, can be utilized, but are usually unnecessary and impractical in general clinical practice.[9,38,69] Blood glucose must be closely monitored in patients with diabetes mellitus, and those with long-standing disease should receive appropriate monitoring for nephropathy, retinopathy, and neuropathy.[9]

ABBREVIATIONS

APACHE	Acute Physiology and Chronic Health Evaluation
BISAP	besdside index of severity in acute pancreatitis
BUN	blood urea nitrogen
CCK	cholecystokinin
CECT	contrast-enhanced computed tomography
CEL	carboxyl ester lipase
CFTR	cystic fibrosis transmembrane conductance regulator gene
CT	computed tomography
ERCP	endoscopic retrograde cholangiopancreatography
EUS	endoscopic ultrasonography
HIV	human immunodeficiency virus
ICU	intensive care unit
MRCP	magnetic resonance cholangiopancreatography
MRI	magnetic resonance imaging
NSAID	nonsteroidal anti-inflammatory drug
PERT	pancreatic enzyme replacement therapy
PRSS1	protease serine 1 (trypsin 1) gene
SIRS	systemic inflammatory response syndrome
SPINK1	serine peptidase inhibitor Kazal type 1 gene
VIP	vasoactive intestinal peptide

SELF-ASSESSMENT QUESTIONS

1. Which of the following etiologies of acute pancreatitis is the most common in the United States?

   A. Gallstones

B. Medications

C. Alcohol

D. ERCP

2. Which of the following medications has a probable association as a cause of acute pancreatitis?

A. Pravastatin

B. Opiates

C. Hydrochlorothiazide

D. Bactrim

3. Which of the following is correct concerning the course of acute pancreatitis?

A. About half of patients have a severe course with a mortality rate over 50%.

B. The gold standard for identifying patients at risk for a severe course is serum lipase.

C. There is no role for CECT in the diagnosis or staging of acute pancreatitis.

D. Scoring systems combine multiple factors to predict the clinical course of acute pancreatitis.

4. Which of the following is correct regarding fluid replacement in acute pancreatitis?

A. Patients at risk for renal or cardiovascular complications should be fluid restricted.

B. Fluid and electrolyte requirements are minimal in patients with mild disease.

C. Guidelines recommend 5-10 mL/kg/hr of initial fluid replacement.

D. Sequestered fluid in the peritoneal or retroperitoneal space should not be replaced.

5. Which of the following is the best nutrition therapy for a patient who is on hospital day 5 with slowly resolving severe acute pancreatitis?

A. Oral nutrition with a low-fat diet

B. Enteral nutrition support via the nasogastric route

C. Total parenteral nutrition

D. Combined enteral and parenteral nutrition

6. Which of the following is correct with respect to the use of opioid analgesics for pain associated with acute pancreatitis?

A. Avoid agents that cause spasm of the sphincter of Oddi.

B. Morphine is often used due to longer duration of action.

C. Synthetic opioids are the preferred agents.

D. Merperidine is the agent of choice.

7. Which is of the following is correct regarding studies evaluating the use of prophylactic antibiotics in acute pancreatitis?

A. No benefit is present in acute pancreatitis without infection.

B. Studies using carbapenems show a decrease in pancreatic infection.

C. The largest studies have the greatest benefit.

D. Studies enrolling patients without necrosis show a decrease in mortality.

8. Which of the following cell types are thought to be a primary cause of the pathogenesis of chronic pancreatitis?

A. B cells

B. Macrophages

C. T cells

D. Stellate

9. Which of the following imaging studies should be used first along with clinical signs and symptoms in the diagnosis of chronic pancreatitis?

A. CT

B. MRCP

C. EUS

D. ERCP

10. Which of the following is the best recommendation for a 47-year-old man with chronic pancreatitis who smokes and still has steatorrhea despite maximum pancreatic enzyme supplementation?

A. Begin a histamine-2 receptor antagonist.

B. Quit smoking and begin fat-soluble vitamin supplementation.

C. Begin a proton pump inhibitor, quit smoking, and reduce fat intake.

D. Switch enzyme supplement and maintain current fat intake.

11. Which of the following is the best therapy for treating pain from chronic pancreatitis in a 51-year-old woman with a past medical history of a bleeding gastric ulcer who is no longer getting relief from acetaminophen 650 mg orally four times daily?

A. Fentanyl 25 mcg/hr transdermal patch every 72 hours

B. Hydrocodone/acetaminophen 5/500 mg orally four times daily

C. Ibuprofen 400 mg orally three times daily

D. Tramadol 50 mg orally four times daily

12. Which of the following patients with chronic pancreatitis is the best candidate for pancreatic enzyme supplementation?

A. Steatorrhea with persistent weight loss

B. Steatorrhea without weight loss

C. Fecal fat estimation of 2 g/day

D. Worsening pain despite opioids

13. Which of the following pancreatic enzyme supplement dose forms could be administered through an enteral feeding tube in an acidic solution?

A. Minitablets

B. Enteric-coated beads

C. Microspheres

D. Microtablets

14. Which of the following is the best option for a patient with persistent steatorrhea who has not gained weight despite receiving the maximum dose of microsphere enzyme supplements administered during meals?

A. Change to minitablets

B. Add an antisecretory agent

C. Administer supplements before meals

D. Administer supplements with applesauce

15. Which of the following should regularly be assessed in a patient receiving opioids for pain associated with chronic pancreatitis?

A. Steatorrhea

B. Weight loss

C. Respiratory depression

D. Constipation

SELF-ASSESSMENT QUESTIONS-ANSWERS

1. **A.** Obstruction due to gallstones is the leading cause of acute pancreatitis in the United States, with alcohol misuse being the second most common cause. Although medications and ERCP can cause acute pancreatitis, they are infrequent causes compared to gallstones and alcohol misuse. See Table 57-1 for other etiologies of acute pancreatitis.

2. **C.** Hydrochlorothiazide is classified as having a probable cause of acute pancreatitis. A list of other medications associated with the occurrence of acute pancreatitis and their classification as a likely cause can be found inTable 57-2.

3. **D.** Several scoring systems have been developed to predict the clinical course of acute pancreatitis. They all use multiple pieces of information that usually makes them difficult to use at the bedside.

4. **C.** Guidelines recommend anywhere from 250 to 500 mL/hr to 5 to 10 mL/kg/hr of intravenous fluid for the first 12 to 24 hours during resuscitation in patients with acute pancreatitis.

5. **B.** Current guidelines recommend beginning oral or enteral nutrition within the first 24 to 72 hours of admission in patients with severe acute pancreatitis. If the patient cannot tolerate an oral diet enteral nutrition delivered via the nasogastric route is recommended.

6. **B.** When the utilization of opioids is necessary for pain control in patients with acute pancreatitis, morphine is preferred due to its longer duration of action.

7. **A.** Large studies and meta-analyses show no benefit with prophylactic antimicrobial use in patients with severe acute or necrotizing pancreatitis in patients without signs or symptoms of infection. When infected pancreatitis is suspected, carbapenems is beneficial.

8. **D.** Activation of pancreatic stellate cells is thought to be the primary pathophysiologic mechanism for the development of chronic pancreatitis. Their activation by various mediators leads to fibrin deposition that causes pancreatic duct obstruction.

9. **A.** CT and MRI are recommended first along with clinical signs and symptoms for the diagnosis of chronic pancreatitis. More invasive imaging studies, such as MRCP, EUS and ERCP are recommended when noninvasive studies are inconclusive.

10. **C.** Smoking is strongly associated with the occurrence and risk of chronic pancreatitis, as well as worsening progression of the disease, so smoking cessation should be implemented for this patient. In addition, patients who fail to respond to maximum doses of pancreatic enzyme supplementation should reduce fat intake and have an antisecretory agent, either a histamine-2 receptor antagonist or proton pump inhibitor, added to their medication therapy regimen.

11. **D.** While NSAIDs and acetaminophen are the first-line analgesics recommended for the treatment of pain from chronic pancreatitis, NSAIDs would be contraindicated in this patient with a history of a bleeding gastric ulcer. Tramadol is effective in the treatment of pain from chronic pancreatitis and is recommended before implementation of opioids.

12. **A.** While laboratory studies may be used to assess the effectiveness and guide the dosage of pancreatic enzyme supplementation, clinical signs and symptoms of malabsorption, along with indicators of malnutrition such as weight loss, are used in determining when supplementation should be initiated.

13. **C.** Products composed of microspheres are recommended for administration through enteral feeding tubes when suspended in an acidic solution. This is because they have the smallest particle size compared to products composed of microbeads or mini- or microtablets.

14. **B.** The addition of a histamine-2 receptor antagonist or proton pump inhibitor is recommended when patients with exocrine pancreatic insufficiency fail to show an adequate response to maximum tolerated enzyme supplementation. The increase in gastric pH provided by the use of these agents allows more enzymes to survive the generally acid gastric contents until they reach the duodenum.

15. **D.** Patients prescribed opioids for the pain due to chronic pancreatitis should be assessed regularly for constipation. In addition, they should be prescribed laxatives on as-needed or scheduled basis for episodes of constipation.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 58: Viral Hepatitis

Paulina Deming

KEY CONCEPTS

KEY CONCEPTS

① Hepatitis A virus (HAV) is transmitted via the fecal–oral route, most often from ingestion of contaminated food or water, or through contact with an infected person.

② HAV causes an acute, self-limiting illness and does not lead to chronic infection. There are three stages of infection: incubation, acute hepatitis, and convalescence. Rarely, the infection progresses to liver failure.

③ HAV vaccination is highly effective. There is no pharmacological treatment specifically for HAV; treatment consists of supportive care.

④ Hepatitis B virus (HBV) causes both acute and chronic infection. Chronic infections are responsible for high rates of liver disease, liver cancer, and death.

⑤ Vaccination can prevent HBV and is the most effective strategy in preventing complications of HBV infections. Prevention of HBV infections focuses on immunization of all children and at-risk adults.

⑥ The purpose of anti-HBV drug therapy is for viral suppression and immune control and to prevent progression of liver disease and the complications associated with HBV infections.

⑦ Initial therapy of chronic HBV is with tenofovir or entecavir because these agents have a high barrier to resistance. Therapy is often long term.

⑧ Patients undergoing immunosuppressive therapy or chemotherapy should be screened for HBV infections and may require HBV therapy to reduce the risks of reactivating their HBV and developing fulminant liver failure.

⑨ The hepatitis C virus (HCV) is an insidious, blood-borne infection. Universal, one-time screening is recommended for all persons aged 18 and over.

⑩ Hepatitis C infections can cause significant morbidity (including extrahepatic manifestations) and mortality. Patients with chronic hepatitis C are at risk for end-stage liver disease, cirrhosis, liver transplant, and death as a result of their infection.

⑪ The goal of anti-hepatitis C virus (HCV) drug treatment is cure. Drug therapy with direct-acting antivirals (DAAs) is highly effective and well tolerated.

BEYOND THE BOOK

BEYOND THE BOOK

Watch “Hepatitis C: Test, Treat, Cure” available at: Npaihb.org/hcv/

This short video includes a review of epidemiology of HCV infections, risks for HCV infection, tests for HCV diagnosis, and patient experiences with HCV as well as with HCV treatment.

INTRODUCTION

The major hepatotrophic viruses responsible for viral hepatitis are hepatitis A, hepatitis B, hepatitis C, delta hepatitis (hepatitis D), and hepatitis E. All share clinical, biochemical, immunoserologic, and histologic findings. Hepatitis A and E are spread through fecal–oral contamination, whereas hepatitis B, C, and delta are transmitted parenterally. Infection with delta hepatitis requires coinfection with hepatitis B. This chapter focuses on hepatitis A, B, and C.

Viral hepatitis remains a major cause of morbidity and mortality with a significant impact on healthcare costs in the United States. Compared with human immunodeficiency virus (HIV), there are three to five times as many people infected with chronic viral hepatitis. In the United States, a national strategy for the elimination of hepatitis B and C was established by the National Academies of Science, Engineering, and Medicine.[1] Despite the national strategy, many challenges persist in achieving elimination goals. Although unprecedented therapeutic advances occurred for the treatment for hepatitis C; the rates of acute infection are on the rise and challenges in screening and access to treatment persist. Both hepatitis A and B are vaccine preventable, yet many vulnerable patients remain unvaccinated and susceptible to infection.

HEPATITIS A

Hepatitis A virus (HAV) is often a self-limiting and acute viral infection of the liver posing a health risk worldwide. The infection is rarely fatal. According to the Centers for Disease Control and Prevention (CDC), rates of reported cases of acute clinical HAV infection in the United States were declining until multi-state outbreaks were reported in 2013 and 2016. Since 2016, 38 multi-state outbreaks were reported with an increase of over 1,300% in the number of acute cases. As of May 2021, nearly 40,000 cases were reported with a 61% hospitalization rate and 374 deaths.[2]

Epidemiology

① Infection primarily occurs through the fecal–oral route, by person-to-person, or by ingestion of contaminated food or water. HAV’s prevalence is linked to resource-limited regions and specifically to those with poor sanitary conditions and overcrowding. Travel to areas with poor sanitation poses a risk for travelers. In areas with good sanitation and hygiene, HAV outbreaks are observed among specific patient groups, such as persons who inject drugs (PWID) and in men who have sex with men (MSM). Household or close personal contacts of an infected person are at high risk for infection. Children can contribute to the spread of the disease because they often remain asymptomatic and are infectious for longer periods of time than adults.

In the United States, recent HAV outbreaks were identified in persons who use drugs, persons experiencing homelessness, and in MSM.[3] Foodborne outbreaks occur with local and widespread outbreaks reported annually. Although HAV infections were previously mostly identified in children, since 2018 adults aged 30 to 39 accounted for the highest number of cases, followed by adults aged 40 to 49.[2] In 2019, HAV rates were highest among White, non-Hispanic males aged 30 to 39. Of patients with a known history of risk factors, 46% were linked with injection drug use. Mortality rates are low and were previously recognized to be most likely in elderly patients with underlying comorbid conditions. However, in 2019 death was most likely to occur in males aged 45 and above.[2] Patients with pre-existing chronic liver disease, such as HCV, are at an increased risk of developing fulminant HAV.[4]

Despite low endemic rates and successful vaccination programs in the United States, travel to HAV endemic areas is a recognized risk for acquiring acute HAV infections and includes “standard” tourist itineraries. Rural and backcountry travel or consumption of food or drink in areas of poor sanitation pose the highest travel-related risk.[5]

Etiology

① Hepatitis A is a nonenveloped ribonucleic acid (RNA) virus in the *Picornaviridae* family. The virus is stable in low pH environments and in freezing to moderate temperatures.[5] Inactivation requires disinfecting with a 1:100 dilution of sodium hypochlorite (bleach) in tap water or heating foods to a minimum of 85°C (185°F) for 1 minute.[5] Chlorination of water also effectively kills HAV in water systems. Transmission occurs primarily through the fecal–oral route because HAV is shed in the feces of infected people.[5] Contaminated water or ice are common modes of transmission, as are any foods which may be prepared using contaminated water including shellfish harvested from contaminated water. Access to clean water and proper handwashing are critical in preventing the transmission of HAV.

Pathophysiology

HAV infection is usually acute, self-limiting, and confers lifelong immunity. HAV's life cycle in the human host classically begins with ingestion of the virus. Absorption in the stomach or small intestine allows entry into the circulation and uptake by the liver. Replication of the virus occurs within hepatocytes and gastrointestinal epithelial cells. New virus particles are released into the blood and secreted into bile by the liver. The virus is then either reabsorbed to continue its cycle or excreted in the stool. The enterohepatic cycle will continue until interrupted by antibody neutralization.[5]

Clinical Presentation

② The incubation period of HAV is approximately 28 days, with a range of 15 to 50 days.[5] Table 58-1 summarizes the clinical features of acute hepatitis. There are no specific distinguishing features of HAV compared to other types of hepatitis; thus, serological testing for immunoglobulin (Ig) M antibody to HAV (anti-HAV) is needed to confirm a diagnosis of acute HAV. In the majority of patients, IgM anti-HAV will be detectable within 5 to 10 days of symptom onset. Symptom severity varies according to age. Children younger than 6 years typically are asymptomatic and can shed the virus for long periods of time, serving as a reservoir for the spread of HAV. Peak fecal shedding of the virus precedes the onset of clinical symptoms and elevated liver enzymes. Acute hepatitis follows, beginning with the preicteric or prodromal period. The phase is marked by an abrupt onset of nonspecific symptoms, some mild.[6] More unusual symptoms include chills, myalgia, arthralgia, cough, constipation, diarrhea, pruritus, and urticaria. The phase generally lasts 2 months.

TABLE 58-1

Clinical Presentation of Acute Hepatitis

	Hepatitis A (HAV)	Hepatitis B (HBV)	Hepatitis C (HCV)
Signs and symptoms	>70% of patients are symptomatic with fever, jaundice, and scleral icterus. Hepatomegaly is evident on physical exam. Less common signs include splenomegaly, skin rash, arthralgia.	• Approximately 70% of patients are anicteric or subclinical. Younger patients most likely to be asymptomatic. • If symptoms occur, jaundice, dark urine, white stool, abdominal pain, fatigue, fever, chills, loss of appetite, and pruritus are possible.	Approximately 70% of patients are asymptomatic. If symptoms occur, jaundice, dark urine, white stool, abdominal pain, fatigue, fever, chills, loss of appetite, and pruritus are possible.
Laboratory Findings in Acute Phase of Infection			
Aminotransferase (ALT, AST) Elevations	• >1,000 IU/L (16.7 µkat/L) • ALT>AST	• 1,000-2,000 IU/L (16.7-33.3 µkat/L) • ALT>AST	• Highly variable, can be approximately 1,000 IU/L (16.7 µkat/L) • ALT>AST
Bilirubin	Elevated and preceded by aminotransferase elevations	Can be normal or elevated	Elevated and preceded by aminotransferase elevations
Virus Specific Tests	IgM anti-HAV for acute HAV; IgG anti-HAV for prior infection or vaccination	IgM anti-HBc (+), HBsA g (+) for active, acute infection	HCV RNA (+) or quantifiable; HCV antibody reactive within 12 weeks of exposure

ALT, alanine aminotransferase; anti-, antibody; AST, aspartate aminotransferase; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen; IU, international units; L, liter.

Liver enzyme levels rise in serum within the first weeks of infection, peaking approximately in the fourth week and normalizing by the eighth week. Conjugated bilirubinemia, clinically evident as dark urine, precedes the onset of the icteric period. Gastrointestinal symptoms may persist or subside during this time and some patients may have hepatomegaly. Duration of the icteric period varies and corresponds to disease duration, averaging between 7 and 30 days.[6]

The diagnosis of acute HAV is made through the IgM anti-HAV which is detectable 5 to 10 days prior to symptomatic HAV infections in the majority of patients. The IgG anti-HAV replaces IgM and indicates host immunity following the acute phase of the infection.[6] Serological testing is available for IgM anti-HAV, IgG anti-HAV, and total (anti IgM and IgG) anti-HAV. Patients who have detectable total anti-HAV with a negative IgM have resolved their infection. Concentrations of antibody often fall to 10 to 100 times lower than what would be expected after a natural course of infection. Detectable antibodies may persist for over 40 years. Although a positive anti-HAV result confirms protection, undetectable concentration of anti-HAV may not necessarily imply that protective levels were not achieved.[6] Booster, or challenge doses, may be given after a HAV vaccine series is completed to provide rapid immunity when there is concern for serious infection.[6]

HAV does not lead to chronic infections; however some patients may experience symptoms for up to 9 months. Rarely, patients experience complications from HAV including relapsing hepatitis, cholestatic hepatitis, and fulminant hepatitis. These severe effects are more likely in patients who are immunocompromised, have underlying liver disease, or are greater than 40 years of age.[6] Fatalities from HAV are generally rare, although more likely in patients older than 50 years and in persons with preexisting liver disease.[6]

A diagnosis of HAV is based on clinical criteria of an acute onset of fatigue, abdominal pain, loss of appetite, intermittent nausea and vomiting, jaundice or elevated serum aminotransferase levels, and serologic testing for IgM anti-HAV. Testing for IgM anti-HAV in the absence of symptoms is not recommended.[6] Serologic testing is necessary to differentiate the diagnosis from other types of hepatitis.

Treatment

Desired Outcomes

The majority of people infected with HAV can be expected to fully recover without clinical sequelae.[7] Nearly all individuals will have clinical resolution within 6 months of the infection and a majority will have done so by 2 months. Rarely, symptoms persist for longer or patients relapse. The ultimate goal of therapy is complete clinical resolution. Other goals include reducing complications from the infection, normalization of liver function, and reducing infectivity and transmission. Prevention of HAV infection is important because significant costs are accrued during acute HAV infections, including costs of administration and use of immunoglobulin and vaccine, hospitalizations and indirect costs from loss of workdays.

General Approach to Treatment

③ Prevention and prophylaxis are keys to managing this vaccine-preventable virus. No specific treatment options exist for HAV infections. Instead, patients should receive general supportive care. The importance of good hand hygiene should be emphasized in preventing disease transmission. Passive immunity with Ig is used for preexposure and postexposure prophylaxis. Active immunity is achieved through vaccination. Vaccines were approved for use since 1995 and implemented in the routine vaccination of children, as well as at-risk adults, to reduce the overall incidence of HAV.[6] Despite HAV vaccine availability, vaccine coverage in adults is low.

Prevaccination serologic testing to determine susceptibility is generally not recommended. In some cases, testing may be cost-effective if the cost of the test is less than that of the vaccine and if the person is from a moderate-to-high endemic area and likely to have prior immunity. Similarly, because of high vaccine response, postvaccine serologic testing is not recommended.[6]

Prevention of Hepatitis A

HAV is easily preventable with vaccination. Because children often serve as reservoirs of the disease, vaccine programs have targeted children as the most effective means to control HAV. Two vaccines for HAV are available and are incorporated into the routine childhood vaccination schedule. The Advisory Committee on Immunization Practices (ACIP) recommends expanding vaccine coverage to all children, including catch-up programs for children not previously vaccinated. Vaccination is also recommended for adults. The recommendations were enacted in the attempt to further reduce HAV incidence rates and possibly to eradicate the virus.[6] Complete HAV vaccination recommendations are available from the CDC (Table 58-2).

TABLE 58-2

Recommendations for Hepatitis A Virus Vaccination

- All children at 1 year of age
- Any unvaccinated children ages 2-18 years
- Persons traveling to or working in countries that have high or intermediate endemicity of infection.[a]
- Men who have sex with men
- Users of injection and noninjection drugs
- Persons with occupational risk for infection (eg, persons who work with HAV-infected primates or with HAV in a research laboratory)
- Persons with chronic liver disease including Persons with hepatitis B virus infection, Hepatitis C virus infection
- All previously unvaccinated persons anticipating close personal contact (eg, household contact or regular babysitter) with an international adoptee from a country of high or intermediate endemicity within the first 60 days following the arrival of the adoptee
- Anyone who would like HAV vaccine

[a] Travelers to Canada, Western Europe, Japan, Australia, or New Zealand are at no greater risk for infection than they are in the United States. All other travelers should be assessed for HAV risk.

Data from Reference 6.

Persons at risk for worse outcomes with HAV infection are also recommended to receive vaccination and include persons over the age of 40, persons with immunocompromising conditions, persons with chronic liver disease planning on traveling, and persons with HIV. In response to the HAV outbreaks beginning in 2016, ACIP revised its vaccination recommendations to persons ≥1 years of age who are at risk for HAV infection including PWIDs, persons experiencing homelessness, MSM, or persons at risk for severe outcomes with HAV infection such as persons with chronic liver disease or persons with HIV. Vaccination is recommended in settings providing services to adults in which a high proportion have risk factors for HAV infection such as healthcare settings with a focus on injection or noninjection drug use, group homes, and non-residential day care facilities for developmentally disabled persons.

Vaccines to Prevent Hepatitis A

The inactivated virus vaccines licensed in the United States are the single-antigen HAVRIX® and VAQTA® and the combination of HAV and HBV antigen vaccine TWINRIX®. Both single-antigen vaccines are available for pediatric (12 months and older) and adult (18 years and older) use, while the TWINRIX® is indicated for adults only (Table 58-3). The differences in the vaccines are in the use of a preservative and in expression of antigen content. VAQTA® is formulated without a preservative and uses units of HAV antigen to express potency. HAVRIX® and TWINRIX® use 2-phenoxyphenol as a preservative and antigen content is expressed as enzyme-linked immunosorbent assay (ELISA) units.[6] High seroconversion rates of more than or equal to 94% are achieved with the first dose; however, VAQTA® and HAVRIX® recommend a booster shot to achieve the highest possible antibody titers. Although seroconversion exceeds 90% for HAV after the first dose of TWINRIX®, the full three-dose series is required for maximal HBV seroconversion. An accelerated dosing schedule of TWINRIX® is available but requires four doses for optimal response. The combined vaccine offers the advantage of immunization against both types of hepatitis in a single vaccine.

TABLE 58-3

Recommended Dosing of Hepatitis A Vaccines

Vaccine	Age (Years)	Dose of Hepatitis A Antigen (Volume)	No. of Doses	Schedule[a]
HAVRIX	1-18	720 ELISA units (0.5 mL)	2	0, 6-12 months
	≥19	1,440 ELISA units (1 mL)	2	0, 6-12 months
VAQTA	1-18	25 units (0.5 mL)	2	0, 6-18 months
	≥19	50 units (1 mL)	2	0, 6-18 months
TWINRIX[b]	≥18	720 ELISA units (1 mL)	3	0, 1, 6 months
	≥18 (accelerated schedule)	720 ELISA units (1 mL)	4	0, 7 days, 21-30 days, +12 months

[a] Zero (0) denotes initial dose, subsequent numbers denote time after initial dose for timing of additional doses.

[b] Combination hepatitis A and B vaccine, also contains 20 mcg of hepatitis B surface antigen and requires a three-dose schedule for adequate HBV response.

Data from Reference 6.

In situations of postexposure prophylaxis, either the vaccine or Ig can be used, although vaccine is preferred because it confers the benefit of long-term immunity against HAV. In patients older than 40 years or with underlying medical conditions, vaccine experience is limited, thus vaccine and immunoglobulin may be preferred for optimal protection.[5] Both vaccines may be given concomitantly with Ig and the two brands are interchangeable.[6]

Vaccination is recommended for international travel to areas of high or intermediate endemicity and can be given regardless of scheduled dates of departure. For older patients, immunocompromised, or any patients with chronic liver disease or any other chronic medical conditions traveling within 2 weeks, both Ig and vaccine are recommended.[5] Vaccination is preferred because it confers long-term protection.

The most common side effects of the vaccines include soreness and warmth at the injection site, headache, malaise, and pain. More than 65 million doses of the HAV vaccine have been administered and despite routine monitoring for adverse events, there are no data to suggest a greater incidence of serious adverse events among vaccinated people compared with nonvaccinated. The vaccine is considered safe.[4–6]

Post serological testing after vaccination is not recommended due to the high efficacy of vaccination. However, anti-HAV levels can be measured against a World Health Organization (WHO) standard. Although the lowest level of protective anti-HAV has not been established, a general standard is ≥ 10 mIU/mL (IU/L).[6]

Immunoglobulin

Immunoglobulin (Ig) is a sterile preparation of concentrated antibodies against HAV that provides protection by passive transfer of antibody. In 2017, recommendations for increased dose of Ig were established due to concerns for declining HAV antibody from donors. Active immunity is achieved through vaccination, although preexposure prophylaxis is used in situations where protective effects of vaccine may either be inadequate or take too long to develop. Specifically, Ig is recommended with vaccination if travel to an HAV high or intermediate risk country will begin in <2 weeks and the individual is an older adult, immunocompromised, or has chronic liver disease or other chronic medical condition. Ig is used when preexposure or postexposure prophylaxis against HAV infection is needed in persons for whom vaccination is not an option. Vaccination is preferred for multiple reasons, including that it induces active immunity and, therefore, a longer time of protection against HAV than Ig.

Immunoglobulin is most effective if given in the incubation period of the infection. Receipt of Ig within the first 2 weeks of infection will reduce infectivity and moderate the infection in 85% of patients. Patients who receive at least one dose of the HAV vaccine at least 1 month prior to exposure do not need preexposure or postexposure prophylaxis with Ig.[6] Although Ig is available as both an intravenous (IV) and intramuscular (IM) injection, for HAV exposure only the IM formulation is used.

Serious adverse events from Ig are rare. Anaphylaxis has been reported in patients with IgA deficiency. Patients who had an anaphylaxis reaction to Ig should not receive it. There is no contraindication for use in pregnancy or lactation.

Dosing of Ig is the same for adults and children. For postexposure prophylaxis and for short-term preexposure coverage of less than 3 months, a single dose of 0.02 mL/kg IM is given. For long-term preexposure prophylaxis of less than or equal to 5 months, a single dose of 0.06 mL/kg is used. Either the deltoid or gluteal muscle may be used. In children younger than 24 months, Ig can be given in the anterolateral thigh muscle.[6]

Vaccination is also preferred in most patients who were recently exposed to HAV and who had not been previously vaccinated. In contrast, prophylaxis with Ig may be preferred in patients younger than 12 months or who have an allergy to a vaccine component.[5]

Ig can be given concomitantly with the HAV vaccine. Although the antibody titer will be significantly lower than with the vaccine administered alone, the response is still protective and coadministration should be considered for the advantages of long-term HAV protection. However, Ig can interfere with the response of other live- attenuated vaccines and should be delayed.

Vaccine efficacy may be reduced in certain patient populations. In HIV-infected patients, greater immunogenic response may correlate with higher baseline CD4-cell counts. Patients with lower CD4 counts or HIV viremia at vaccination have a reduced response rate.[7]

HEPATITIS B

④ Viral hepatitis B infections pose a substantial global disease burden. Hepatitis B is highly infectious, approximately 50 to 100 times more so than HIV.[8] In 2015, 3.5% of the population, or 257 million people, had chronic HBV. In comparison, 0.8% of the adult population, or 38 million people, were living with HIV. Screening and diagnosis also vary between the two viral infections- only 10% of patients with chronic HBV are aware of their infection in comparison to 79% of people living with HIV.

Globally, the majority of adults with chronic HBV were infected prior to the availability and use of the HBV vaccine in infancy.[9,10] Chronic infection with HBV is a major public health issue as it serves as a reservoir for continued HBV transmission and poses a significant risk of death resulting from liver disease including liver cirrhosis and hepatocellular carcinoma (HCC). According to the WHO, 650,000 people per year die as a result of complications from HBV.[10] In the United States, there is no national chronic hepatitis surveillance program; however, estimates suggest between 850,000 and 2.2 million people have chronic HBV.[1] Although HBV infection is uncommon among the general population in the United States, prevalence is high among certain groups.

Low public awareness, low perceived risk, and misinformation about HBV can result in discrimination and stigma.[1] In 2013, the Department of Justice recognized patients with chronic HBV infection to be protected under the Americans with Disabilities Act after students with HBV were denied enrollment in health professional schools. Although not curable, HBV infections can be successfully managed with viral suppression. Importantly, vaccination prevents HBV infection. In 2021, the CDC’s ACIP recommended universal HBV vaccination for all adults aged 19 to 59.

Epidemiology

According to the WHO, chronic HBV infections disproportionately affect low- and middle-income countries.[9,10] Prevalence can vary regionally; however, areas commonly associated with high infectivity rates include sub-Saharan Africa, East Asia, followed by the Amazon and southern parts of Eastern and Central Europe.[10] Most new HBV infections are in children in areas of high HBV prevalence, approximately 45% of the global population. Infections of infants and children are of special concern because more than 90% of cases lead to chronic infections and serve as ongoing source of infectivity. Major public health initiatives focused on pediatric vaccination have successfully reduced HBV infection. In the United States, acute HBV cases declined by approximately 90% since vaccination recommendations were first issued in the 1980s.[11] Annual rates of acute cases vary but in 2019, the number of new HBV cases was 20,700. Substantial increases in the number of cases of acute HBV were first reported in 2016 and were attributed to injection drug use and the opioid epidemic. The highest rates of acute HBV continue to be among White non-Hispanic or Black non-Hispanic men between the ages of

30 to 49 years.[2] Injection drug use continues to be the most commonly identified risk factor for new HBV infections, followed by sexual contact.

HBV is transmitted sexually, parenterally, and perinatally because concentration of HBV is high in blood, serum, and wound exudates of infected persons. The virus can be stable in the environment for at least 7 days and can cause infection during this time. Even in the absence of visible blood, HBV can cause infection and transmission may occur through the reuse of contaminated needles, syringes, or sharp objects. In areas of high HBV prevalence, perinatal transmission from mother to child at birth is most common. Horizontal transmission, such as from an infected child to an uninfected child, is also common. In the United States, perinatal transmission and sexual contact continue to be key routes of transmission. Lack of infection control practices specifically related to blood glucose monitoring also contributed to HBV outbreaks in the 2000s and 2010s.[10] Screening recommendations focus on individuals at high risk for HBV including household contacts of an HBV-positive person (Table 58-4).[11]

TABLE 58-4

Persons at High Risk for HBV: Recommended Screening

Individuals from the Following Areas	Other Groups
• Africa (all countries) • Asia (all countries in North, Southeast, East Asia) • South Pacific Islands (all countries except Australia and New Zealand) • Middle East (all countries except Cyprus and Israel) • Malta • Spain • Arctic (indigenous populations of Alaska, Canada, Greenland) • South America (Ecuador, Guyana, Suriname, Venezuela, and Amazonian areas) • Central America (Mexico, Guatemala, and Honduras) • Eastern Europe (all countries except Hungary) • Caribbean (Antigua-Barbuda, Dominica, Granada, Haiti, Jamaica, St. Kitts and Nevis, St. Lucia, Turks and Caicos)	• US-born persons not vaccinated as infants whose parents were born in high HBV endemic regions • Household, needle-sharing, and sexual contacts of HBsAg-positive patients • Infants born to HBsAg-positive mother • Persons who have ever injected drugs • Persons not in a long-term mutually monogamous relationship (>1 partner in previous 6 months) • Persons seeking evaluation or treatment for an STD • Men who have sex with men • Inmates of correctional facilities • Individuals with chronic liver disease • Individuals with elevated AST or ALT of unknown etiology • Individuals with HIV or HCV • Patients with end-stage kidney disease including those receiving dialysis • All pregnant women • Persons requiring immunosuppressive therapy (chemotherapy, organ transplantation, rheumatological, or gastroenterologic) • Donors of blood, plasma, organs, tissues, or semen • Unvaccinated persons with diabetes aged 19-59 years (clinical discretion for persons >60 years) • Residents/staff of facilities for developmentally disabled persons • Travelers to countries of high or intermediate HBV prevalence • Healthcare, public safety workers at risk for occupational exposure to blood or blood-contaminated body fluids • Persons who may require postexposure prophylaxis following blood or fluid exposures

ALT, alanine aminotransferase; AST, aspartate aminotransferase; HBsAg, hepatitis B surface antigen; STD, sexually transmitted disease.

Data from Reference 11.

Up to half of all children infected before the age of 6 will develop chronic HBV.[9] Children infected in the first year of life have a 90% likelihood of developing chronic HBV infection; thus, prevention of perinatal transmission and pediatric vaccination is critical.

Etiology

The HBV is a deoxyribonucleic acid (DNA) virus that infects hepatocytes.[12] There are at least 10 HBV genotypes (GTs) (A-J) with distinct geographic and ethnic distribution. Although particular HBV GTs can affect the course of HBV infections, testing for HBV GT is not recommended for clinical practice.[13]

Pathophysiology

On infection, replication of the virus begins by attachment of the virion to the hepatocyte cell surface receptors. The virion contains an internal capsid shielding a partially double stranded DNA which is released within the hepatocyte nucleus and integrates into the host chromosomal DNA.[12] In the nucleus the DNA is converted into closed, circular DNA that serves as a template for pregenomic RNA to transcribe various viral proteins and begins the viral life cycle. The viral genome has four reading frames coding for various proteins and enzymes required for viral replication. Several of these proteins are used diagnostically (Table 58-5).

TABLE 58-5

Interpretation of Serologic Tests in Hepatitis B Virus

Tests	Result	Interpretation
HBsAg	(–)	Susceptible
Anti-HBc	(–)	
Anti-HBs	(–)	
HBsAg	(–)	Past HBV infection, resolved
Anti-HBc	(+)	No further management needed unless undergoing immunosuppressive therapy or chemotherapy
Anti-HBs	(+)	
HBsAg	(–)	Immune because of vaccination (valid only if test performed 1-2 months after third vaccine dose)
Anti-HBc	(–)	
Anti-HBs	(+)	
HBsAg	(+)	Acute infection
Anti-HBc	(+)	
IgM anti-HBc	(+)	
Anti-HBs	(–)	
HBsAg	(+)	Chronic infection.
Anti-HBc	(+)	Further evaluation needed
IgM anti-HBc	(–)	
Anti-HBs	(–)	
HBsAg	(–)	Possible interpretations: (1) Resolved infection or (2) false positive. If patient immunocompromised, check
Anti-HBc	(+)	HBV DNA[a]
Anti-HBs	(–)	

[a] Some patients may experience occult HBV infection, defined by the presence of low-level HBV DNA levels in the setting of negative HBsAg.

Note: Unless otherwise specified, anti-HBc includes total (both IgM anti-HBc and IgG anti-HBc) or IgG anti-HBc. IgM anti-HBc is present during acute phase of infection.

Anti-, antibody; HBc, hepatitis B core; HBs, hepatitis B surface; HBsAg, hepatitis B surface antigen.

Data from References 12,58.

The hepatitis B surface antigen (HBsAg) is the most abundant of the three surface antigens and is detectable at the onset of clinical symptoms. Its persistence past 6 months after initial detection corresponds to chronic infection and indicates an increased risk for cirrhosis, hepatic decompensation, and HCC. Patients with detectable HBsAg are considered to have active HBV infection. The loss of HBsAg (defined as negative or non-reactive HBsAg) is a goal of therapy and considered an optimal endpoint because it indicates that viral replication and protein expression is suppressed. The loss of HBsAg may occur with or without the development of antibody to HBsAg (anti-HBs).[13]

The precore polypeptide encodes for the secretory protein hepatitis B e-antigen (HBeAg) and the hepatitis B core antigen (HBcAg) proteins. HBeAg is present in an acute infection. In children, HBeAg is responsible for chronic HBV infection because it promotes immune tolerance to HBV.[12] In patients where HBeAg is replaced by antibodies (anti-HBe), the HBV DNA is undetectable, and alanine aminotransferase (ALT) levels normalize, the HBV infection is considered to be resolving. If after a year the patient continues to have HBeAg seroconversion (HBeAg is replaced by anti-HBe), the HBV DNA remains undetectable and the ALT levels remain in the normal range, antiviral therapy may be discontinued with close follow to monitor for HBV reactivation.[14]

The HBcAg is a nucleocapsid protein that, when expressed on hepatocytes, promotes immune-mediated cell death. It is not readily detectable by current laboratory techniques, instead antibodies to HBcAg (anti-HBc) are used for diagnostic purposes. High levels of antibodies (IgM anti-HBc) are detectable during acute infections. Patients who were infected with HBV at any point will be anti-HBc positive (either as total or IgG anti-HBc). Patients who respond to vaccine will have anti-HBs only.[10]

Some patients can have HBeAg negative chronic HBV infections. Due to substantial genetic variability of HBV and propensity for viral mutation, there are viral mutants that have down-regulated expression of HBeAg without affecting viral replication.[12] HBeAg-negative mutants pose a particular clinical challenge because they are refractory to treatment and have been implicated in acute liver failure.[12] Patients with HBeAg-negative mutants will continue to have detectable HBV DNA.

Immune response to HBV affects patient outcomes. In patients who have acute resolving infections, a robust immune response is necessary to quickly neutralize and destroy infected cells before the virus can infect other hepatocytes.[13] Chronic infections are associated with a progressive impairment in immune response. Liver injury is likely caused by secondary, nonspecific inflammation activated by the initial cytotoxic lymphocyte response and as an attempt by the immune system to clear the virus by destroying HBV antigen–presenting hepatocytes. HBV itself is not pathogenic to hepatocytes.[12] Destruction of hepatocytes results in release of circulating, and hence increased ALT levels.

Chronic Hepatitis B Virus

④ Chronic HBV is defined as detectable HBsAg for more than 6 months.[11] Chronic infections can be controlled in many cases, but cure is not possible because the HBV template is integrated into the host genome. The most predictive factor for developing a chronic infection is age. Perinatal infections almost always result in chronic infections because of immune tolerance to the virus. The risk of chronicity declines to less than 5% in adult-onset infections. Importantly, chronic HBV infections are often dynamic and disease progression may not necessarily be sequential.[13]

Clinical Presentation and Phases of Infection

The clinical symptoms and course of a HBV infection are indistinguishable from other types of viral hepatitis (Table 58-1).

During the initial phase of the infection, profuse HBV DNA replication results in high levels of HBV DNA and HBeAg secretion (positive or detectable levels of HBeAg). Patients with HBV >1 million IU/ml (kIU/L) are highly contagious.[13] This phase has been described as "immune tolerant" because hepatic injury is limited.[11] ALT levels remain within normal limits (historically defined as <40 IU/L [0.67 µkat/L]) and no or minimal evidence of fibrosis is seen on liver biopsy.[13] In perinatal or early childhood infections, the phase can persist for years and the likelihood for spontaneous HBeAg seroconversion (loss of HBeAg) is low.[13]

As the immune system responds to HBV-infected hepatocytes, ALT elevants may be intermittent or persist. This immune activity against HBV-infected hepatocytes can lead to liver injury with progression of fibrosis.[11,13] During this time high levels HBeAg and HBV DNA may be present. This phase is more likely in adults and progresses more rapidly.[13] With the increase in immune activity against HBV-infected hepatocytes, the outcome can include HBV DNA suppression. Another scenario where immune response is minimized to the infection is characterized by undetectable or low (<2,000 IU/mL [kIU/L]) HBV DNA, reactive antibody to HBeAg (anti-HBe positive), and normal ALT. Progression of liver disease is unlikely in this phase if ALT remains persistently normal. However, some patients will not see immune control of HBV.

A less common state, described as HBeAg negative chronic HBV, is characterized by viral mutation. Mutations within the virus result in loss of HBeAg production but viral replication is not affected and HBV DNA levels range from moderate to high. ALT levels can also fluctuate or be elevated and patients have more advanced liver disease. Guidelines recognize this mutation in HBV with a lower threshold for initiating HBV treatment.

An uncommon but important clinical state is the "occult HBV infection," where HBcAg (Anti-HBC) antibody is positive with negative HBsAG, yet HBV DNA is present, frequently in low levels. Patients may or may not have detectable anti-HBs and the ALT levels are often within normal limits. The risk of ongoing liver damage is minimal unless HBV reactivation occurs, such as if a patient is started on immunosuppressive therapies which may allow rapid increases in HBV replication.[14–16]

Reactivation of hepatitis B, defined as the recurrence or abrupt rise in HBV replication by an increase in serum HBV DNA of at least 1 $\log_{10}$ and a marked increase in transaminase levels, is well described in the literature in patients receiving cancer chemotherapy, steroids, and other immunosuppressive agents.[15,16] Reactivation is the loss of HBV immune control and can occur in anyone with a prior or current HBV infection, but patients who are HBsAg positive are at particular risk. Patients who are HBsAg positive and undergoing treatment with B-cell depleting agents (eg, rituximab), anthracycline derivatives (eg, doxorubicin), or moderate-to-high dose steroid therapy (10-20 mg per day of prednisone or equivalent for 4 weeks or longer) are considered high risk for reactivation.[15] Risk of reactivation is especially high among patients undergoing B-cell depleting therapy (eg, rituximab), where reactivation can occur even in the setting of HBsAg negativity but anti-HBc positivity.[15] Antiviral prophylactic therapy is often indicated to prevent reactivation and continued for at least 6 months, or at least 12 months for B cell–depleting agents, after discontinuation of immunosuppressive therapy.[15]

Cirrhosis

Cirrhosis results as the liver attempts to regenerate while in an environment of persistent inflammation, such as HBV or HCV infections. The development of cirrhosis is mostly insidious and patients can remain stable for years before disease progression. Most patients with compensated cirrhosis either are asymptomatic or have mild symptoms of epigastric pain. The diagnosis is made by laboratory or imaging findings. A decline in albumin, increase in bilirubin, and/or increase in prothrombin time (PT)/international normalized ratio (INR), and/or evidence of portal hypertension (thrombocytopenia) typically demonstrate a gradual decline in synthetic function as blood perfusion through the liver is affected. On imaging, the classical appearance of a small and knobby liver reflects nodules of regenerating cells integrated with infiltrates of inflammation-induced fibrous tissue. Progression of liver disease is variable and affected by both viral and host factors; in particular, the immune response to HBV plays a key role in clinical outcomes (Table 58-6). Patients without cirrhosis have a 5% to 20% risk of progression to cirrhosis over a 5-year period. Subsequently, 20% of all patients with chronic hepatitis B infection and cirrhosis progress to decompensated cirrhosis within a 5-year period.[13] Progression to decompensated cirrhosis is marked by the development of clinical complications of hepatic insufficiency and portal hypertension such as ascites or hepatic encephalopathy. Risks for death and decompensation increase with underlying liver disease. All patients with cirrhosis, irrespective of severity or receipt of HBV treatment, are at an annual risk of developing HCC and require routine surveillance for HCC as per guidelines.[11]

TABLE 58-6

Factors Associated with Hepatitis B Virus Cirrhosis and Risk of HCC

Host Factors	Viral Factors
Older age at diagnosis	Persistence of high HBV serum DNA and or HBsAg levels
African ancestry (greater likelihood for early onset HCC)	Infection with genotype C > B
Asian ethnicity	Specific HBV mutations
Alcohol misuse	
Chronic coinfection with HCV, delta hepatitis, or HIV	
Diabetes or metabolic syndrome	
Active smoking	
Family history of cirrhosis/HCC Presence of cirrhosis (as a risk for HCC)	

Data from References 13 and 17.

Hepatocellular Carcinoma

HBV is a known risk factor for the development of HCC and in areas of high HBV endemicity, a major complication of the infection.[9] There is a known annual risk of developing HCC in patients with cirrhosis because of the years of inflammatory processes provoked by ongoing HBV infection. Several factors influence the development of HCC (Table 58-6), in particular, the presence of cirrhosis. In the United States, the majority of cases of HCC are in patients >60 years of age, male, with cirrhosis, and of Asian race. Patients of African ancestry are more likely to develop HCC at a younger age (median 44 years).[17] HBV itself is an oncogenic virus and HCC can occur in patients with HBV who do not have cirrhosis.[9]

Vaccine Prevention of Hepatitis B

⑤ Vaccination is the most effective strategy to prevent HBV infection. Despite substantial declines in HBV, gaps in HBV vaccination persist that contribute to ongoing HBV transmission. Birth dose vaccination of infants born to HBsAg-positive women remains below the 85% target for Healthy People 2020.[18] Similarly, the three-dose vaccine coverage for adults, including patients with chronic liver disease, travelers, persons with diabetes, and healthcare personnel are lower and far below target levels.[19] Vaccination for HBV is less effective than for HAV and requires multiple doses for improved response Many patients start a vaccine series but do not complete it. All infants and all previously unvaccinated children less than 19 years of age should receive HBV vaccine. Additionally, in 2021 ACIP voted to recommend universal HBV vaccination for all adults aged 19 to 59. Adults 60 and older are recommended for vaccination based on risk factors (Table 58-7).

TABLE 58-7

Risk Factors for Hepatitis B Virus Infections: Adult 60 and Older Vaccination Recommendations

- All unvaccinated adults aged 19-59 with diabetes; those aged >60 should be vaccinated at the discretion of treating clinician
- Sex partners of persons who are HBsAg positive
- Sexually active persons not in a long-term monogamous relationship (>1 partner/6 months)
- Men who have sex with men
- STD clinic patients
- Persons with HIV
- Current or recent injection drug use
- Household contacts of persons with chronic hepatitis B infection; clients and staff of institutions for the developmentally disabled
- Healthcare and public safety workers with anticipated risk for exposure to blood or blood-contaminated fluid in the workplace
- Chronic dialysis/ESRD patients including predialysis, peritoneal dialysis, and home dialysis patients
- Correctional facilities inmates
- International travelers to regions with high or intermediate levels (HBsAg prevalence >2%) of endemic HBV infection
- Persons with chronic HCV infection
- Persons with chronic liver disease (eg, patients with alcoholic liver disease, cirrhosis, fatty liver disease, autoimmune hepatitis)
- All unvaccinated adults seeking vaccination (specific risk factor not required)

ESRD, end-stage renal disease.

Data from Reference 19.

The development of the HBV vaccine represented the first vaccine against a major human cancer.[9] Vaccines use HBsAg to prompt active immunity. The HBsAg is produced using recombinant DNA technology using yeast. The HBsAg itself is not infectious; only the complete HBV is infectious. Available vaccines include HBV antigen only products and combination products. The two single-antigen products are Recombivax® HB and Engerix-B®. The PreHevbrio™ vaccine, approved in 2021, contains three hepatitis B surface antigens to elicit a more robust vaccine response. TWINRIX® is a combination vaccine for HAV and HBV in adults. Comvax® and Pediarix® are used for children along with other scheduled vaccines. Unlike the HAV vaccine, the HBV vaccine response is generally lower and often requires at least three doses for optimal protection. Most vaccines use aluminum as an adjunct; however in 2017 the Food and Drug Administration–approved the Heplisav-B® vaccine which uses a novel adjuvant for immunogenicity, a toll-like receptor ligand to enhance immunity that allows for a two-dose vaccine schedule in adults (Table 58-8).

TABLE 58-8

Recommended Dosing of Hepatitis B Vaccines (HBV Antigen Vaccines)

Vaccine	Age (Years)	Dose (Volume)	No. of Doses	Schedule[a]
Engerix-B	0-19	10 mcg IM (0.5 mL)	3	0, 1, 6 months
	>20	20 mcg IM (1 mL)	3	0, 1, 6 months
Recombivax	1-19	10 mcg IM (0.5 mL)	3	0, 1, 6 months
	>20	10 mcg IM (1 mL)	3	0, 1, 6 months
Heplisav-B[b,c]	≥18	0.5 mL	2	0, 1 months
PreHevbrio[c]	≥18	1 mL	3	0, 1, 6 months

[a] Zero (0) denotes initial dose, subsequent numbers denote time after initial dose for timing of additional doses.

[b] Utilizes different adjuvant; cannot be interchanged with other HBV vaccines.

[c] Cannot be interchanged with other HBV vaccines.

Data from Reference 6.

The most commonly reported adverse events for single-antigen vaccine are nausea/dizziness, and fever/headache; for combination vaccines, fever, injection site erythema, and vomiting. For Heplisav-B, the most common adverse reactions reported within 7 days of vaccination included injection site pain, fatigue, and headache.

Vaccination is the standard for HBV prevention. Passive immunity with hepatitis B Ig offers temporary protection against HBV and is used in conjunction with the hepatitis B vaccine for postexposure prophylaxis in infants born to HBsAg-positive mothers and for select other prophylaxis.[19]

Treatment

Desired Outcomes

⑥ Prevention of HBV, in particular preventing mother-to-child transmission, is a primary goal with substantial public health benefits. HBV infections are not curable; thus, the goals of therapy are to suppress HBV replication and prevent disease progression to cirrhosis and HCC. Another important goal is preventing HBV reactivation in patients with inactive HBV infections.

General Approach to Treatment

⑥ HBV viral suppression is a goal of all therapies.[13] In patients who are HBeAg positive, HBeAg loss, with or without seroconversion to anti-HBeAg, indicates immune control. Normalization of ALT is another goal associated with viral suppression. An ultimate goal of therapy is the loss of HBsAg with or without anti-HBs seroconversion. This is a goal not often realized but one associated with suppression of HBV replication and viral protein expression and indicates antiviral therapy that can be safely discontinued.

Indications for treatment consider HBV DNA levels, ALT levels, and whether or not the patient has cirrhosis (Table 58-10). All patients with cirrhosis require HBV treatment, irrespective of DNA or ALT levels. In patients without cirrhosis, HBV DNA and ALT levels can determine the need for treatment because active viral replication predicts disease progression.[13] In persons without cirrhosis, elevated ALT levels are used to recognize inflammation within the liver and thus the need for HBV treatment to minimize disease progression. Not all persons with chronic HBV are candidates for treatment. Persons without cirrhosis who have low levels of HBV DNA (<2,000 IU/mL [kIU/L]) may be managed by periodic monitoring. The rationale for deferring HBV treatment includes the concern that therapeutic response is unlikely and does not outweigh the risks and costs associated with treatment. The major organizations providing comprehensive guidelines on the management of HBV infections are the WHO, American Association for the Study of Liver Diseases (AASLD), the European Association for the Study of the Liver, and the Asian Pacific Association for the Study of the Liver. A more simplified approach to treatment for primary care providers is also available through the online resource from the HBV Primary Care Workgroup (https://www.hepatitisb.uw.edu/page/primary-care-workgroup/guidance).

TABLE 58-10

Generally Accepted Criteria for Treatment of HBV

Characteristics:

Anyone with HBeAg (+) or HBeAg (−) active HBV defined as:

- HBV DNA >2,000 IU/mL (kIU/L)
- ALT 2 × upper limit of normal[a] and/or with evidence of histological disease[b]

Anyone with compensated or decompensated cirrhosis with HBV DNA >2,000 IU/mL (kIU/L)[c]

- Anyone not fulfilling above criteria with ALT < 2 × ULN and any detectable HBV DNA (<2,000 IU/mL [kIU/L]), consider:
- Patient's age
- Family history of HCC
- Prior history of HBV treatment Extrahepatic manifestations of HBV

[a] Per European guidelines, any elevations in ALT.

[b] Moderate or greater fibrosis as determined by biopsy or noninvasive measures.

[c] Per European guidelines, any detectable HBV DNA.

Patient Counseling and Nonpharmacologic Therapy

All persons with chronic HBV should be counseled on preventing disease transmission. Sexual and household contacts should be vaccinated against HBV. Barrier protection methods are recommended for sex partners who have not completed vaccination series.[11] Concomitant metabolic syndrome and insulin resistance increase hepatic liver disease progression and the development of HCC.[20,21] Other lifestyle factors known to potentiate liver disease include alcohol use and smoking.[11,20] Herbal medicines are an intriguing option to many patients, although no data support their use and some may have harmful effects on liver function.

Pharmacologic Therapy

HBV virological cure, or HBV virus eradication, is not an achievable goal of therapy because of persistence of the closed, circular DNA in hepatocytes and lifelong risk for HBV reactivation. Instead, the loss of HBsAg and the development of anti-HBs is considered a "functional cure" because it indicates a loss of HBV replication. This is a rare event even in patients on HBV therapy and rarely occurs spontaneously in the absence of HBV therapy.[10]

Because hepatic damage is sustained by ongoing viral replication, drug therapy aims to suppress viral replication by either antivirals—the nucleos(t)ide agents (NAs)—or immunomodulating agents. A major difference in therapy between the NAs and the immune-mediating agents is duration of use: interferon (IFN)-based therapies are typically administered for a predefined duration, whereas NAs are used until a specific end point is achieved. Antiviral agents are the preferred therapy for several reasons, including that they are all oral agents, are well tolerated, and can be safely used even in patients with decompensated cirrhosis.[22]

The preferred NAs are those considered to have a high barrier to resistance and include entecavir, tenofovir diprovoxil, and tenofovir alafenamide. All of these agents also have some level of activity against HIV; thus, it is important to understand a patient's HIV status before starting HBV therapy.

In the United States, the immune-mediating agents approved for use are pegylated interferon (peg-IFN)-alfa and IFN-alfa. These agents are injectable. Due to the substantial side effects, need for monitoring, and toxicities of IFN-based therapies, their role in HBV treatment is limited. IFN is not recommended as a first-line therapy by the WHO.[9]

Entecavir

7 Entecavir is an oral guanosine analogue that inhibits the HBV polymerase, thus preventing HBV replication. It has weak activity against HIV.[9] Entecavir is considered to be a first-line agent for HBV therapy because of its efficacy and low rates of resistance.[8,10,12,13] It is more potent than lamivudine and adefovir in suppressing serum HBV DNA levels, improving liver histology, and normalizing ALT levels.[9] Rates of HBeAg seroconversion increase with subsequent years of treatment.[13] The dose is 0.5 mg orally daily for adults with treatment-naïve or non–lamivudine-resistant infections and 1 mg daily in lamivudine-experienced patients or patients with decompensated cirrhosis. Entecavir resistance remains low in treatment-naïve persons, demonstrating the high barrier to resistance of the drug.[13] However, resistance to lamivudine is a risk factor for entecavir resistance; thus, guidelines do not recommend use of entecavir in patients with prior lamivudine experience.[11] Entecavir is safe and well tolerated.

Tenofovir

7 Due to its high barrier to resistance, tenofovir is considered a first-line therapy in the treatment of HBV.[11,13] For HBV, it is available as a single-agent oral tablet. Tenofovir is a nucleotide analog which competitively inhibits HBV polymerase, thus interrupting viral replication. There are two forms of tenofovir available: tenofovir disoproxil fumarate (tenofovir DF) and tenofovir alafenamide. Tenofovir DF is available as a 300-mg dose for HBV. Tenofovir alafenamide is a prodrug converted to the active tenofovir in the hepatocyte, allowing for a lower dose at 25 mg. Tenofovir DF was used for HBV where it was highly effective in HBV DNA viral suppression demonstrating regression of fibrosis.[10,23] It is effective even in patients previously treated with other HBV therapies. Tenofovir DF is associated with acute renal injury and hypophosphatemia, thus renal function should be monitored before and during treatment.[11] It is also associated with decreased bone mineral density. In persons with suspected tenofovir DF renal or bone disease, HBV treatment should be switched to entecavir or tenofovir alafenamide.

Tenofovir alafenamide offers several advantages over tenofovir DF as it allows more efficient delivery of tenofovir directly to the hepatocytes and thus a more direct action against HBV replication. In both HBeAg- positive and HBeAg-negative patients, tenofovir alafenamide was as effective as tenofovir DF and was more likely to result in normalization of ALT.[24] The ability to reduce the systemic exposure to tenofovir allows for an improved safety profile. Compared to tenofovir DF, tenofovir alafenamide demonstrated improved bone safety and smaller changes in estimated glomerular filtration rates.[24]

Resistance to tenofovir has not been seen in clinical studies. No resistance was identified to tenofovir DF through a 7-year study period and viral suppression was seen in nearly all patients, regardless of HBeAg status.[23] Similarly, there was no resistance to tenofovir alafenamide with 96 weeks of follow-up.[25]

Alternative Drug Treatments

Other available NAs which have a low barrier to resistance and are thus not preferred for treatment of HBV include lamivudine, telbivudine, and adefovir.[11] Lamivudine has antiviral activity against both HIV and HBV but is not recommended as first-line therapy for chronic HBV infections. The main limitation to lamivudine use is its likelihood for resistance, which is considered inevitable and can undermine the value of treatment. Adefovir's role in HBV therapy is unclear. It is no longer recommended as monotherapy because it also has a relatively low barrier to resistance. Telbivudine is similar to lamivudine and also has a high rate of mutations that limits its efficacy. It has been discontinued in the US market. Combination therapy has been proposed for chronic HBV treatment; however it is not recommended for initial HBV treatment.[13] Patients who are treatment adherent but have incomplete HBV DNA viral control on entecavir or tenofovir DF/tenofovir alafenamide should be switched to the other drug. In rare instances combination therapy can be considered, such as if adherent patients continue to have suboptimal HBV DNA viral suppression or in patients with multiple underlying HBV resistance mutations.[11,13,26] If combination therapy is considered, guidance should be sought from a clinician with expertise in HBV treatment.

Special Populations

Cirrhosis

All patients with cirrhosis should receive HBV treatment irrespective of HBV DNA, HBeAg status, or ALT elevations. The presence of cirrhosis is a risk for worsening complications of end-stage liver disease thus an independent reason to initiate HBV treatment. Patients with decompensated cirrhosis should be on HBV therapy and evaluated for liver transplant.[11] Recommended therapies in patients with decompensated cirrhosis include entecavir and tenofovir DF. There are no data using tenofovir alafenamide in patients with decompensated cirrhosis; however, if renal function or bone disease is a concern, it is reasonable to use tenofovir alafenamide. Treatment in these patients is continued indefinitely.[11]

Coinfection with Hepatitis C Virus

Coinfection with HCV increases the progression of liver disease including the risk of HCC; thus, all patients with HBV should be screened for HCV. Moreover, reactivation of HBV can occur in patients undergoing treatment with direct-acting antivirals (DAAs) for HCV and may require HBV prophylaxis.[11,13] The exact mechanism of this is unknown but is primarily a concern in patients undergoing HCV DAA therapy who also have detectable HBsAg. Patients with both HBV and HCV should be evaluated for HBV treatment according to HBV treatment criteria.

Coinfection with Hepatitis D

Infection with hepatitis D requires infection with hepatitis B. No NAs have demonstrated efficacy against HDV; however, IFN does have some efficacy against HDV and treatment may include either IFN monotherapy or a combination of IFN with an NA.[9,13]

Coinfection with Human Immunodeficiency Virus

In HIV-coinfected patients, initiation of highly active antiretroviral therapy (HAART) is strongly recommended as it may improve overall survival. Therapy should include either tenofovir alafenamide or tenofovir DF since both have efficacy against HIV and HBV.[13]

Pediatric Patients

Most children with chronic HBV are asymptomatic and do not meet the established criteria for HBV treatment.[13] Treatment is recommended in HBeAg-positive children aged 2 to 18 who have elevated ALT and measurable HBV DNA.[11] A limitation to the recommendations is a lack of clarity regarding the upper limit of normal for ALT in pediatric patients with guidelines using an upper limit of normal of 35 IU/L (0.58 µkat/L) for males and 25 IU/L (0.42 µkat/L) for females.[11] Entecavir and tenofovir DF are approved for children 2 years and older and are preferred due to their high barrier to resistance. Adefovir and lamivudine are not preferred due to the low barrier to resistance. Although IFN is approved for use in children 1 year and older, its side effect profile and need for injection limits its use.

Chronic HBV in Pregnancy

Perinatal transmission of HBV is a major cause of chronic HBV. In pregnant females who are HBeAg positive and have an HBV DNA >200,000 IU/mL (kIU/L), tenofovir DF is recommended in the third trimester. Tenofovir alafenamide has been shown to prevent transmission with no safety concerns in one small retrospective study, and may be a potential option once additional evidence is available.[27] To prevent mother-to-child transmission, all infants born to HBsAg-positive women should receive HBV vaccination and immunoglobulin within 12 hours of birth.[19] Assessment of HBsAg status, a complete HBV vaccine series, and post-vaccination serological testing to document vaccine response (anti-HBs) is recommended. Revaccination is recommended in infants who are HBsAg negative and do not have a post-vaccination anti-HBs titer ≥10 mIU/mL (IU/L). Infants born to females with an unknown HBsAg status should also receive the first dose of vaccine within 12 hours of birth while maternal serological tests are pending. The rationale for this birth dose vaccination approach is that timely prophylaxis against HBV can disrupt the vertical transmission associated with perinatal HBV infections. Completion of the vaccine series is critical to long-term HBV prevention.

Immunosuppressive or Cytotoxic Therapy

8 Patients who will undergo chemotherapy or immunosuppressive therapy should be assessed for risk of HBV. The American Gastroenterological Association recommends antiviral prophylaxis for persons who are at high risk of HBV including persons who are (1) HBsAg-positive or negative and anti-HBc-positive and undergoing B-cell depleting agents such as rituximab; (2) HBsAg-positive and anti-HBc-positive treated with anthracycline derivatives such as doxorubicin; (3) HBsAg-positive and anti-HBc-positive undergoing 10 to 20 mg prednisone daily or equivalent therapy or on high-dose (>20 mg prednisone daily or equivalent) corticosteroids for 4 weeks or more.[15,16] Due to moderate risks of reactivation, other immunosuppressive therapies such as tumor necrosis factor alpha inhibitors, cytokine or integrin inhibitors, tyrosine kinase inhibitors, and corticosteroids are also identified as requiring antiviral prophylaxis in patients with specific HBV serological results.[15,16] The CDC recommends testing for hepatitis B for all patients who are to receive chemotherapy or other immunosuppressive agents.

8 Patients who are at high risk of HBV reactivation and are expected to be on chemotherapy or immunosuppressive treatment for 1 year or less should receive prophylactic HBV antiviral therapy and be treated for at least 6 months after completion of chemotherapy or immunosuppressive therapy..[15]

Hepatitis B Virus Mutations and Resistance Concerns

Although a DNA virus, HBV uses reverse transcriptase, similar to a retrovirus such as HIV. The similarities between HIV reverse transcriptase and HBV polymerase prompted the development of NAs for the treatment of HBV. The preferred therapies have a high barrier to resistance. Resistance potential in HBV is evaluated by an antiviral agent's genetic barrier to resistance, or the number of primary mutations needed for antiviral drug resistance to occur. Other factors include cross-resistance and drug potency. Treatment adherence is important.

Viral resistance in HBV is a concern given HBV's high replication rate and an estimated 10 mutations generated daily.[9–11] Viral suppression is important because the HBV virus mutates and risks the development of resistance when ongoing viral replication occurs in the setting of antiviral drug pressure.

Patients who experience treatment interruptions risk treatment failure because HBV can archive drug-resistant mutations that allow the virus to quickly select the mutation if the antiviral agent is reintroduced. Cross-resistance among antiviral agents also occurs, further limiting therapeutic options. Lamivudine is most commonly associated with resistance due to (1) its low barrier for developing resistance with a single mutation able to overcome efficacy and (2) widespread use of lamivudine in some regions.[9]

Resistance to the NA agents occurs by alteration of the active site of the HBV DNA polymerase. Long-term use of lamivudine is associated with resistance mutations of this active site and cross-resistance occurs which also affects telbivudine.[28] Prior treatment with lamivudine and the expected resistance with ongoing lamivudine therapy is an established risk for entecavir resistance. In these patients with prior lamivudine experience, a tenofovir-based therapy is preferred due to concerns for entecavir resistance. Resistance to tenofovir alafenamide was not identified in clinical trials and is rare is clinical practice.[25]

Guidelines favor the use of entecavir, tenofovir DF, and tenofovir alafenamide because these are potent agents able to suppress viral replication and maintain a high barrier to resistance. However, another major factor in resistance is patient adherence to therapy. Barriers to adherence include forgetting doses, limited understanding of the importance of adherence, and changes to routine.[29]

HEPATITIS C

Approximately 2.4 million people in the United States are chronically infected with HCV.[2] Considering that HCV infection is prevalent in high-risk populations such as prisoners, PWIDs, and homeless individuals, and that this population is generally excluded from most surveys, the actual number of chronically infected people is not known. Routine screening for HCV remains a barrier to diagnosis given the substantial stigma associated with HCV. Most acute HCV infections are asymptomatic. Chronic infections are often insidious, leading to delays in HCV diagnosis and significant disease progression. The current HCV epidemic is linked to the opioid crisis. HCV therapies are curative in the overwhelming majority of patients. These treatments are all-oral and well tolerated with few adverse effects or laboratory abnormalities. However, HCV treatment access is variable and may include a number of stipulations which act as barriers to care and ultimately, the ability to cure HCV.

Epidemiology

⑨ ⑩ HCV is the most common blood-borne pathogen. Since 2010, the number of acute HCV cases increased, due to both improved surveillance and increase in incidence. There were 50,300 new HCV infections in 2018 compared to 16,500 in 2011.[2] Since 2014, acute HCV cases increased by 71% and most were among people aged 20 to 39. Universal HCV screening is recommended for all persons aged 18 and older by the CDC and the United States Prevention Services Task Force, in an attempt to address this rising epidemic.[30]

Transmission of HCV occurs through percutaneous exposure.[31] Injection-drug use is a major factor in the cycle of HCV transmission and the most common reason for the current increase in new infections. In Indiana in 2015, an outbreak of 135 new cases of HIV among PWIDs identified coinfection with HCV in over 84% of patients.[32] Some experts also consider other illicit drug use, for example, intranasal cocaine, as a risk factor because of the possible contamination of drug paraphernalia not limited to syringes and needles. Unsafe injection practices are associated with HCV transmission and include tattoos received in a nonregulated setting and needle stick injuries. Less common routes of transmission include sexual transmission and infants born to HCV-infected women.[33] Although sexual contact is considered an inefficient means of HCV transmission, anal sex, multiple sexual partners, and coinfection with sexually transmitted diseases, including HIV, increase the risk for HCV sexual transmission. Outbreaks of HCV were demonstrated in MSM with guidelines recommending annual HCV screening for adolescent and adult MSM including HIV-uninfected men seeking HIV preexposure prophylaxis.[31] Blood transfusion posed a major risk for infection, but improved screening of blood in 1992 decreased the risk of transfusion-related HCV.[31] Healthcare-associated transmission is rare; however, unsafe injection practices are often identified as the cause of HCV transmission.

⑨ The CDC recommends hepatitis C screening at least once in all adults aged 18 and above.[30] More frequent screening is recommended if there are risk factors for infection (Table 58-11). Because of the increase in HCV infections among women of reproductive age, HCV screening should also be done with each pregnancy.[30] The AASLD, in conjunction with the Infectious Diseases Society of America (IDSA), publish online guidelines for testing, managing, and treating HCV (see www.hcvguidelines.org).[31] The AASLD recommends children born to mothers with HCV be screened at or after 18 months of age. More frequent screening is also warranted in persons who are at high risk for infection, especially among PWIDs or who have a history of injection drug use (Table 58-11).[31] Any needle-borne exposure in an unregulated setting poses a risk for infection.

TABLE 58-11

Recommendations for Hepatitis C Virus Screening

All adults ≥ 18 years
All pregnant females during each pregnancy
Routine periodic testing for persons with ongoing risk factors:

- Persons who inject drugs, share needles, syringes, or other drug preparation equipment
- Persons undergoing maintenance hemodialysis
- Sexually active MSM with HIV
- MSM at initiation of HIV pre-exposure prophylaxis

Data from References 30 and 31.

The initial test for HCV infection is the anti-HCV or antibody test (Fig. 58-1). Patients who are antibody positive for HCV require confirmatory testing for HCV RNA to verify current HCV infection. Some laboratories offer reflex testing where confirmatory testing is done on all samples where the anti-HCV is reactive. Patients who are anti-HCV positive but who do not have a detectable HCV RNA do not have a current HCV infection and no further workup is required in the majority of cases.[34] The presence of antibody does not infer immunity and patients are at risk for HCV infection should they be reexposed.[35]

Etiology

HCV is a single-stranded RNA virus notable for lacking a proofreading polymerase which enables frequent viral mutations and poses a challenge for vaccine development.[35] The virus replicates within hepatocytes and, like hepatitis B, is not directly cytopathic. HCV replicates copiously posing an immense challenge for host immune control.[35] Viral mutations can affect DAA therapy.

HCV is differentiated into seven major GTs, numbered 1 to 7. GTs are further classified into subtypes (a, b, c, etc.). The most widely distributed GTs are 1 and 2, with GT1 being the most common. In the United States, GT1a and GT1b, followed by GT2 and GT3, cause most infections. Chronic HCV infection with any of the GTs can lead to cirrhosis, end-stage liver disease (ESLD), or HCC. Preferred therapies on most formularies are those that are pan-genotypic (active against all GTs).

Pathophysiology

In most cases, an acute HCV infection leads to chronic infection. The immune response in an acute HCV infection is mostly insufficient to eradicate the virus. HCV poses a daunting challenge for immune control because of its rapid viral diversification. Resolved cases of HCV are defined by a vigorous T-cell response with highly active CD8 and persistent CD4-cell response. CD8 activity mediates protective immunity but requires the aid of CD4 cells to maintain the response during viral mutations.[35]

Clinical Presentation

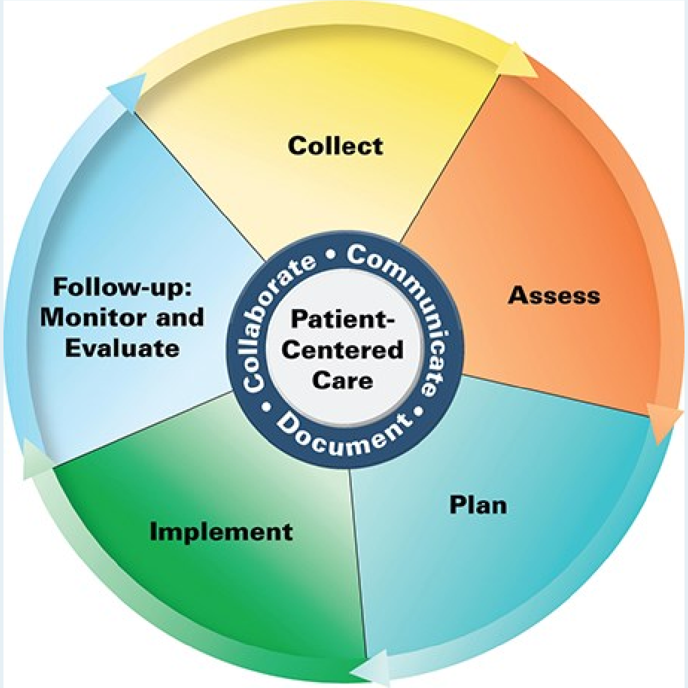
In an acute HCV infection, most patients are asymptomatic and thus undiagnosed. HCV RNA is detectable within 1 to 2 weeks of exposure and levels rise quickly during the initial weeks. Approximately one-third of adults will experience some mild and nonspecific symptoms of hepatitis, including fatigue, anorexia, weakness, jaundice, abdominal pain, or dark urine.[36] Acute infections rarely progress to fulminant hepatitis, although the course can be severe and prolonged. Patients who have self-limiting infections may experience symptoms as the immune response attempts to clear the infection. This can result in clinical symptoms and elevated ALT levels. If symptomatic, patients generally see symptom improvement as ALT and HCV RNA levels subside. In patients who are immunosuppressed or have been infected with HCV for less than 6 months, antibody testing could be negative because the immune system is unable or has not yet developed an antibody response. In these cases, confirmation of HCV infection requires HCV RNA testing.[31]

Up to 85% of acutely infected patients will go on to develop a chronic HCV infection, defined as persistently detectable HCV RNA for 6 months or more. HCV RNA levels and ALT levels can fluctuate. Most patients will have few, if any, specific symptoms of chronic HCV infection. Chronic inflammation of the liver from chronic HCV infection may result in fibrosis. Fibrosis is defined by altered hepatic perfusion creating a distorted structure and affecting normal function. Fibrosis leads to cirrhosis, although the speed of fibrosis progression is variable. Patients with cirrhosis require follow-up care specifically for management of the complications associated with cirrhosis. Once a patient is diagnosed with cirrhosis, staging is necessary to differentiate patients who have compensated cirrhosis (Child's class A cirrhosis) versus decompensated (Child's class B or C cirrhosis). Patients with decompensated cirrhosis generally require management by specialists due to severe liver damage and potential complications.

10 The development of HCV cirrhosis poses a 30% risk over 10 years for the development of ESLD, as well as a 1% to 2% risk per year of developing HCC.[30] Progression to cirrhosis is the primary concern in patients infected with HCV for two decades or longer. Disease progression is not uniform or linear, making it difficult to identify which patients will have progressive liver damage and when. Other concomitant viral infections, comorbidities, and lifestyle factors can contribute to disease progression. Ongoing alcohol use, obesity, and metabolic syndrome can potentiate fibrosis.[31] Viral load is not a factor for disease progression and not associated with degree of fibrosis. Coinfection with HIV or HBV is associated with disease progression as is infection with HCV GT3.[31,37]

10 Although HCV is thought of as a liver disease, chronic HCV is associated with extrahepatic manifestations, or HCV-associated systemic disease. The most common is cryoglobulinemia, a local deposition of immune complexes that cause vasculitis.[31] Typical manifestations involve the skin and internal organ damage, predominantly affecting the kidneys and associated with worsening renal function. Other systemic diseases associated with HCV include cardiovascular disease, diabetes, B-cell non-Hodgkin lymphoma, Sjögren syndrome, glomerulonephritis, arthritis, corneal ulcers, thyroid disease, neuropathies, and skin diseases such as vasculitis, porphyria cutanea tarda, and lichen planus.[38]

Patient Care Process for Hepatitis C



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient history (past medical, family, social) and medical record summary
- Thorough medication history (include prescription, nonprescription medications, and other substances) and drug allergies and intolerances. Previous HCV therapy, if applicable.
- Laboratory results (see Table 58-1)
- Laboratory results to assess if patient has cirrhosis (see Table 58-2)
- Abdominal imagining or transient elastography results (if available)

Assess

- Determine if the patient is a candidate for the simplified treatment algorithm (see Table 58-3)
- If the patient has cirrhosis, assess the level of liver dysfunction using the Child-Pugh Score to determine options for HCV therapy
- Review insurance company formulary preferences for HCV therapy
- Review national guidelines for updated treatment recommendations
- Assess if patient assistance programs may be utilized

Plan*

- Determine goals of therapy with monitoring parameters for each goal
- Based on severity of underlying liver disease, determine the appropriate therapy, treatment duration, and monitoring plan
- Counsel patients on avoiding pregnancy and need for contraception during treatment
- Identify potential obstacles to treatment success such as insurance requirements regarding refills
- Check for drug interactions with prescribed medications, any over-the-counter medications, herbals, or supplements

Implement

- Initiate HCV direct-acting antiviral (DAA) therapy
- Discontinue or modify adjunct medications if drug interactions anticipated with HCV DAAs
- Discuss with the patient and patient's family what to expect for monitoring while on therapy, strategies to address any potential adverse effects and strategies to minimize likelihood for therapy interruptions

Follow-Up: Monitor and Evaluate

- Continually reassess patient's use of HCV antivirals, any changes in other medications or herbals and supplements which could compromise HCV therapy, and any adverse effects
- Patients not on the simplified algorithm require monitoring of laboratory tests
- Monitor for any interruptions in therapy which could risk treatment failure
- Evaluate patient for cure at least 12 weeks after completion of therapy
- Reassess patient's risk for reinfection and counsel on harm-reduction strategies

* ***Collaborate with patients, caregivers, and other healthcare professionals.***

Treatment

Desired Outcomes

⑪ The primary goal of therapy is to eradicate HCV infection. Virologic cure, or sustained virologic response (SVR), is defined as a nondetectable HCV RNA at least 12 weeks after completing HCV therapy. Patients who achieve SVR will continue to have detectable HCV antibody indefinitely. The persistence of HCV antibody should not be confused with the potential to reactivate HCV and it does not confer protection against subsequent exposure to HCV. Patients can be reinfected with the same or different HCV GT. Resolving the infection prevents the development of chronic HCV infection sequelae including ESLD, HCC, and death. Patients with extrahepatic manifestations of HCV are expected to benefit with reductions in symptoms and disease severity of their extrahepatic disease while experiencing improvements in quality of life measures.[31] As more patients are cured, the risk of transmission is expected to decline and reduce HCV disease prevalence.[31]

General Approach to Treatment

Treatment for HCV is recommended for all persons with HCV. Initiating HCV therapy early in the disease state can provide substantial benefit by preventing complications of liver disease as well as preventing extrahepatic manifestations of HCV. In persons at high risk of transmitting HCV such as PWIDs, HCV treatment may help reduce rates of HCV transmission.[31] There are no clearly identified contraindications for HCV therapy. Patients with a short-life expectancy who are unlikely to benefit from HCV therapy, liver transplantation, or other directed therapy are the only populations for whom treatment is not recommended.[31]

The initial evaluation for HCV treatment is intended to stage the patient's level of liver disease, specifically to differentiate patients with cirrhosis from those without (Table 58-12). Patients without cirrhosis may be candidates for a much more simplified treatment approach if the patient does not have cirrhosis, is HCV treatment naïve, has no history or suspicion of HCC, has not received a liver transplant, and has no evidence of HIV or active HBV infection (Table 58-13). In contrast, patients with cirrhosis must be further evaluated to determine if the cirrhosis is compensated (Child–Turcotte–Pugh [CTP] A) or decompensated (CTP B or C). Patients with cirrhosis will likely require on-treatment monitoring as well as additional post-treatment follow up to manage the complications associated with cirrhosis (eg, need for endoscopy or screening and surveillance for HCC). Patients with decompensated cirrhosis should be treated by clinicians with expertise in managing advanced liver disease.[31]

TABLE 58-12

Tools used for Assessment of Cirrhosis

Any of the Following	
FIB-4 score[a]	Scores >3.25 suggestive of cirrhosis
Transient elastography	Scores >12.5 kPa indicate cirrhosis
Clinical evidence of cirrhosis	Liver nodularity and/or splenomegaly on imaging; thrombocytopenia (platelets <150,000/mm^3 [150 x 10^9/L]); etc.
Serological tests (eg. FibroSure)	Scores above specific test thresholds
Prior biopsy findings[b]	

[a] FIB-4 includes age, AST, ALT, and platelet level.

[b] Biopsy not required for diagnosis of cirrhosis.

TABLE 58-13

Simplified Treatment Candidates

Candidates for Simplified Treatment Approach		
HCV treatment naïve	AND	- No cirrhosis - No coinfection with HIV or active HBV infection - Not pregnant - No history or suspicion of HCC - No history of liver transplant

The suggested laboratory tests prior to treatment are listed in Table 58-14. Quantitative HCV RNA testing is performed to confirm HCV infection. Genotyping is often performed although not required per national guidelines. Patients should be evaluated for HAV and HBV and offered vaccinations if not previously vaccinated. On-treatment laboratory monitoring is not necessary for patients without cirrhosis who meet the criteria for the simplified algorithm. Patients with cirrhosis may need on-treatment monitoring, with the most monitoring required for patients undergoing HCV therapy with the addition of ribavirin.

TABLE 58-14

Suggested Laboratories Prior to Initiating HCV Treatment

Test	Timeframe	Comments
HCV RNA	Any point before starting HCV therapy	Confirm HCV infection
Complete blood count	Within 6 months of starting HCV therapy	Thrombocytopenia (platelets <150,000/mm^3 [150 x 10^9/L] suggest cirrhosis)
Liver function tests	Within 6 months of starting HCV therapy	Albumin, bilirubin used to assess synthetic function of liver and for calculating Child Pugh in patients with cirrhosis; AST/ALT used to assess level of liver inflammation
International normalized ratio	Within 6 months of starting HCV therapy	In patients with cirrhosis used to assess synthetic function of the liver and for calculating Child–Pugh score
Estimated glomerular filtration rate	Within 6 months of starting HCV therapy	Renal insufficiency may indicated extrahepatic manifestations of HCV
HIV antigen/antibody	Any point before starting HCV therapy	Patients with HIV are not candidates for simplified algorithm; HIV and HCV share common routes of transmission (injection drug use)
Hepatitis B serologies (anti-HBs, anti-HBc, HBsAg)	Any point before starting HCV therapy	Patients with detectable HBsAg are at risk for HBV reactivation; patients who are HBV susceptible should be offered HBV vaccine
Anti-HAV	Any point before starting HCV therapy	Patients susceptible to HAV should be offered HAV vaccine

Data from Reference 31.

Counseling and Nonpharmacologic Therapy

Lifestyle changes are an important factor in reducing health consequences in hepatitis C. Continued alcohol use is a known risk factor for disease progression and severity. There is no established lower limit of alcohol consumption at which disease progression is not seen. Obesity is also a factor and patients should be encouraged to eat a balanced diet and exercise regularly to maintain a normal weight. Progression of fibrotic changes is associated with obesity. The use of herbal therapy is ineffective and potentially a source of drug interaction with HCV therapies. Patients should be counseled on minimizing HCV transmission risks and harm reduction strategies are recommended by national guidelines.[31]

Pharmacologic Therapy

⑪ The treatment of chronic HCV was revolutionized with the approval of DAAs. The DAAs act on one of three targets on the HCV virion. The DAAs must be used in combination with at least two drugs acting on different targets. The drug nomenclature identifies where the drug is inhibiting viral replication: the N3/4A protease inhibitors end with –previr; NS5A inhibitors end with –asvir; and the NS5B polymerase inhibitors end with –buvir. Early DAAs acted on specific HCV GTs. Sofosbuvir/velpatasvir, glecaprevir/pibrentasvir, and sofosbuvir/velpatasvir/voxilaprevir are pangenotypic, meaning they are effective in all HCV GTs. The ability to treat without pretreatment GT testing favors the use of these agents and is an increasingly appealing strategy because it can streamline HCV treatment and reduce costs. As a group, the DAAs are well tolerated and cause few laboratory abnormalities.

The guidelines offer a simplified treatment algorithm which takes advantage of the safety and efficacy of pangenotypic therapies and shortened duration of therapy with either an 8- or 12-week treatment course (Table 58-15).[31] Patients who do not have cirrhosis or any other major medical comorbidity are candidates for the simplified treatment (see Table 58-16 for exclusion criteria). Laboratory monitoring is not necessay; patients are re-assessed 12 weeks after the end of therapy with an HCV RNA and LFTs. A negative HCV RNA 12 weeks after completing treatment is consistent with cure, or sustained virologic response (SVR or SVR12 to denote that the HCV RNA was done 12 weeks after completing treatment). The LFTs are determined to confirm resolution of inflammation and identify patients which may need futher workup of their liver disease if inflammation persists.[31]

TABLE 58-15

AASLD/IDSA Recommended Treatment Regimens for Treatment-Naïve Patients with Hepatitis C (All Genotypes)

Simplified Treatment Algorithm		
Glecaprevir/pibrentasvir 3 tabs orally daily with food × 8 weeks	Or	Sofosbuvir/velpatasvir 1 tab orally daily with or without food × 12 weeks
Repeat HCV RNA and LFTs 12 weeks after completing HCV therapy to assess for cure (SVR) and resolution of hepatic inflammation		

Data from Reference 31.

TABLE 58-16

AASLD/IDSA Recommended Treatment Regimens for Treatment-Naive Patients with No Cirrhosis (NC) or Compensated Cirrhosis (CC) and Hepatitis C Genotypes 1-6

	GT1a NC	GT1a CC	GT1b NC or CC	GT2 NC or CC	GT3 NC	GT3 CC	GT4 NC or CC	GT5, 6 NC or CC
DAA Therapy								
Glecaprevir/Pibrentasvir	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Ledipasvir/Sofosbuvir	Yes	Yes	Yes	No	No	No	Yes	Yes
Sofosbuvir/Velpatasvir	Yes	Yes	Yes	Yes	Yes	Yes[b]—but with RAS testing	Yes	Yes
Elbasvir/Grazoprevir	No[a]	No	Yes	No	No	No	Yes	No

[a] Considered an alternative regimen because NS5A resistance testing is required prior to treatment start.

[b] Pre-treatment resistance testing for NS5A resistance associated substitutions (RAS) should be done; if the Y93 RAS identified, an alternative therapy is recommended.

Data from Reference 31.

Patients without cirrhosis or those with compensated cirrhosis are treated similarly with no difference in treatment duration. A main difference in the treatment approach is the necessary monitoring. Patients with cirrhosis may have laboratories (eg, AST/ALT) checked every 4 weeks while on treatment to monitor their underlying liver disease. In contrast, patients with decompensated cirrhosis (CTP class B or C) often require concomitant ribavirin and have fewer treatment options due to the underlying level of liver disease and concerns for safety. In general, patients with decompensated cirrhosis should be managed by clinicians with experience with end-stage liver disease due to the potential for complications related to cirrhosis (eg, ascites, encephalopathy) developing while on HCV treatment.[31]

Prior treatment experience does not substantially alter retreatment except that there are more limited options for retreatment if patients were previously treated with more recent DAA therapies. Patients previously treated with IFN or IFN and a first generation protease inhibitor (boceprevir, teleaprevir, or simeprevir) who did not achieve cure can be retreated with a DAA therapy and expect cure rates comparable to those in patients who are treatment naïve. As a result the national guidelines no longer recognize separate recommendations for IFN-experienced patients. For patients previously treated with a DAA therapy (sofosbuvir- or NS5A-based regimen) who experience treatment failure, the only recommended retreatment is with the combination of sofosbuvir/velpatasvir/voxilaprevir.[31]

Clinically significant drug–drug interactions are expected with carbamazepine, phenobarbital, phenytoin, oxcarbazepine, rifampin, and St. John's wort and concurrent use of these agents with any of the HCV therapies is expected to result in HCV treatment failure. The use of statins is variable and clinical management can vary from holding statins during HCV therapy to changing or dose reducing the statin. An important resource for timely and updated guidance on HCV-drug interactions is available for free through the University of Liverpool: https://www.hep-druginteractions.org/checker

Previously, HCV treatment included the injection of peg-IFN and was associated with a substantial side-effect profile as well as a prolonged duration of therapy. The current standard of care for all chronic HCV infections, regardless of GT, is an all-oral drug regimen. Despite the change in pharmacological therapy, many patients are aware of the substantial side effects associated with IFN-based therapy and are wary of all HCV therapy. For patients familiar with IFN treatment, it is important to clearly distinguish current therapies from IFN-based ones as the concern for side effects of IFN based HCV therapy can prevent patients from seeking HCV treatment with DAAs.

Sofosbuvir

Sofosbuvir was approved in 2013 for HCV GT1 to 4 at a dose of 400 mg. Although available as a single product, its use is mostly as the backbone of combination therapies including ledipasvir/sofosbuvir, sofosbuvir/velpatasvir, and sofosbuvir/velpatasvir/voxilaprevir. Sofosbuvir is metabolized to its primary circulating active metabolite GS-331007. Sofosbuvir is well tolerated and has few drug–drug interactions; the majority of drug interactions are related to the agents used in combination with sofosbuvir. Serious symptomatic bradycardia was identified in patients treated with sofosbuvir and taking amiodarone in combination with other DAAs; thus, this combination is not recommended.

Ledipasvir/Sofosbuvir

The fixed dose combination tablet of ledipasvir/sofosbuvir (90 mg/400 mg) is a recommended therapy in patients with HCV GT1 or 4. A 12-week treatment course is highly effective in treatment-naïve patients with or without cirrhosis with an estimated SVR of 95%.[39] Initial studies also demonstrated a high SVR of 94% in patients without cirrhosis, treatment-naïve, and with a baseline viral load of less than 6 million IU/mL (kIU/L) treated for 8 weeks. However, due to limited data the level of evidence to support this shorter course of therapy is lower than the 12-week course of treatment and the shorter course is not recommended in patients who have cirrhosis, have a viral load greater than 6 million IU/mL (kIU/L), are Black, or have HIV–HCV coinfection.[31,40] There are no differences in treatment whether patients have GT1a, 1b, or 4; however, there are differences in treatment duration depending on underlying cirrhosis.[41,42] The use of ribavirin did not affect SVR rates and is not routinely recommended. Patients with decompensated cirrhosis are more difficult to treat with lower SVR rates. In these patients, ledipasvir/sofosbuvir plus ribavirin is recommended for 12 weeks of treatment. If patients are unable to tolerate ribavirin due to its hematological effects, ledipasvir/sofosbuvir for 24 weeks is an alternative.[31,43] National guidelines also recommend ledipasvir/sofosbuvir for treatment of HCV GT4 for a 12-week course of therapy.[31]

The combination of ledipasvir/sofosbuvir is well tolerated and can be used in patients with cirrhosis, including CTP Class A, B, and C cirrhosis. It may also be used in patients with renal insufficiency including patients with end-stage renal disease on dialysis. Headache and fatigue are the most common side effects. Laboratory abnormalities do not frequently occur. The drug–drug interaction potential is also limited, although amiodarone use is not recommended because of the symptomatic bradycardia observed with the concomitant use of sofosbuvir. Acid suppressive therapy poses a challenge to treatment because ledipasvir requires an acidic environment for absorption. Antacids must be spaced apart by 4 hours whereas histamine blockers should be taken either at the same time or 12 hours apart from ledipasvir/sofosbuvir. The use of proton pump inhibitors is controversial with omeprazole 20 mg once daily recommended by the manufacturer; however, more frequent dosing or higher dosages are expected to compromise the efficacy of ledipasvir.[44] The effect of other proton pump inhibitors is not established and concomitant histamine blockers or antacids must be timed appropriately to avoid a clinically significant drug–drug interaction.

Sofosbuvir/Velpatasvir

Sofosbuvir/velpatasvir is a pan-genotypic agent with activity against GT1 to 6. It is available as a fixed-dose tablet (400 mg/100 mg for adult dosing or 200mg/50 mg for pediatric dosing) and as oral pellets for pediatric use (200 mg/50 mg or 150 mg/37.5 mg). In patients with HCV GT1, 2, 4, 5, and 6 99% SVR was achieved with sofosbuvir/velpatasvir, irrespective of prior treatment experience or whether patients had cirrhosis or not.[40] In GT3 patients, pretreatment resistance testing is recommended for any patients with cirrhosis or prior treatment experience with peg-INF and ribavirin. If the Y93 substitution is detected, ribavirin should be added or an alternative therapy chosen.[31] Studies showed a numerically higher SVR in patients with HCV GT3 and cirrhosis who had received concomitant ribavirin, although this did not reach statistical significance.[45]

Sofosbuvir/velpatasvir is well tolerated with few side effects or laboratory abnormalities. It is recommended for use in patients with all levels of liver disease including decompensated cirrhosis where it is used in combination with ribavirin in order to maximize SVR. Patients with HCV GT1, 2, 3, 4, or 6 and decompensated liver disease treated with sofosbuvir/velpatasvir and ribavirin for 12 weeks achieved an SVR of 94%.[46] Patients with decompensated cirrhosis who cannot tolerate ribavirin may be treated with an extended duration of sofosbuvir/velpatasvir alone for 24 weeks. Most patients with decompensated cirrhosis also demonstrated an improvement in their liver disease (eg, reductions in their Child–Pugh score) as a result of treatment. Sofosbuvir/velpatasvir may also be used in patients with renal impairment, including patients on dialysis. Velpatasvir, like ledipasvir, requires an acidic environment for absorption; thus, patients must be appropriately counseled to avoid the use of proton pump inhibitors and on timing of other acid suppressive therapy to minimize the drug–drug interaction.

Elbasvir/Grazoprevir

Elbasvir/grazoprevir as a fixed-dose tablet (50 mg/100 mg) is approved for use in patients with HCV GT1 and 4. In treatment-naïve patients with HCV GTs 1, 4, and 6, the overall SVR rate was 95%.[47] Among patients with HCV GT1a, SVR rates were lower than for GT1b and this difference was attributed to the presence of baseline resistance–associated substitutions (RASs). When comparing patients with GT1a versus 1b who did not have any RASs, there was no difference in SVR (99 vs 100% SVR, respectively). For patients with baseline RASs and GT1a, the SVR rate dropped to 58%. Therefore, in patients with HCV GT1a, pretreatment resistance testing is required. If specific mutations are identified, treatment must be modified to include ribavirin and extended to 16 weeks, thus making it an alternative treatment as per guidelines in favor of shorter, ribavirin-free treatments.[31] Elbasvir/grazoprevir is approved for use in patients with HCV GT1 or 4, including those with renal insufficiency receiving hemodialysis. Because it contains a protease inhibitor, it should not be used in patients with decompensated cirrhosis.

Glecaprevir/Pibrentasvir

Glecaprevir/pibrentasvir is a pan-genotypic agent with activity against the major HCV GTs. It is available as a combination tablet (100 mg/40 mg) and as oral pellets (50 mg/20 mg) for pediatric use. It is recommended for use in both treatment-naïve and treatment-experienced patients with HCV GTs1 to 6. It is also recommended for use in patients with renal insufficiency including patients on hemodialysis. For patients who are treatment naïve, without cirrhosis or with compensated cirrhosis (CTP class A), the combination is recommended for an 8-week treatment regimen.[31] The approved combination tablet demonstrated the highest SVR rates ranging from 94% to 100% in patients with HCV GTs1 to 6. The lowest SVR at 94% was seen in patients with HCV GT3.[48] An 8-week treatment course is recommended for patients with cirrhosis and HCV GT1 to 6 due to SVR results comparable to those seen in patients without cirrhosis.[49] A smaller number of patients with cirrhosis and HCV GT3 in the clinical trial led to a lower level of recommendation for the use of the 8-week treatment course in these patients.[31] Baseline mutations for NS3 or NS5A did not affect SVR in clinical trials.[50] Because it contains a protease inhibitor, glecaprevir/pibrentasvir should not be used in patients with decompensated cirrhosis due to concerns for worsening liver injury, including liver failure.

Although approved for use in patients with prior DAA failure, guidelines limit the use of glecaprevir/pibrentasvir in this patient population pending further data.[31] Glecaprevir/pibrentasvir is recommended in patients with prior NS3/4A treatment experience (eg, boceprevir or simeprevir). However, it is an alternative treatment for patients with prior NS5A (eg, ledipasvir) treatment in part due to limited data and the need for an extended 16-week treatment duration in this patient population.[31]

Similar to other DAAs, glecaprevir/pibrentasvir is not associated with laboratory abnormalities and is well tolerated. The most common adverse events include headache and nausea. It is contraindicated with ethinyl estradiol products including hormone replacement and oral contraceptives due to a potential for ALT increases.

Sofosbuvir/Velpatasvir/Voxilaprevir

The addition of the pangenotypic protease inhibitor voxilaprevir to sofosbuvir/velpatasvir represents the first triplet regimen against all three targets on the HCV virion. It is available as a combination tablet (100 mg voxilaprevir/400 mg sofosbuvir/100 mg velpatasvir). Although effective in both treatment-naïve and treatment-experienced patients, the triplet regimen is reserved for patients who have failed prior DAA therapies and represents the last available combination for HCV therapy.[31] Although sofosbuvir/velpatasvir can be safely used in patients with decompensated cirrhosis, due to the presence of the protease inhibitor voxilaprevir, the triplet regimen cannot be used in patients with decompensated cirrhosis.

In patients with HCV GT1 to 6 who were previously treated with a DAA course including an NS5A agent, a retreatment course of sofosbuvir/velpatasvir/voxilaprevir achieved an SVR of 99%.[51] A lower SVR was seen in patients with cirrhosis at 93%; however, baseline resistance mutations were not associated with reduced SVR. The combination is also recommended in patients with HCV GT3 who are more difficult to treat including patients with cirrhosis or a known Y93 mutation (ie, patients with prior treatment experience with peg-INF and ribavirin tested for GT3 mutations).[31]

Ribavirin

Ribavirin continues to be used in combination with DAAs, although its use has been minimized when alternative treatments are available that are highly effective and ribavirin-free. There are some situations that continue to require ribavirin in order to improve SVR rates, such as in patients with decompensated cirrhosis or those with HCV GT3. The mechanism of action of ribavirin is not well understood. Ribavirin is a synthetic guanosine analog and is ineffective as a monotherapy for HCV. The most common adverse effect of ribavirin is hemolytic anemia, necessitating close monitoring during HCV therapy and contributing to complaints of fatigue during treatment. In addition, ribavirin is a teratogenic agent, Pregnancy Category X, and women of childbearing age as well as female partners of male patients who undergo HCV treatment with ribavirin need to practice two forms of contraception during HCV treatment and for 6 months after to avoid pregnancy.[31]

Special Populations

Clinical trials are conducted with a patient population that generally does not reflect the patient spectrum encountered in clinical practice. HCV infections are associated with patients who may be less likely to be engaged in routine healthcare and underrepresented in clinical trials. Treatment guidelines address some of these higher risk populations and include recommendations for enhanced screening as well as treatment.[31] Published recommendations for treatment in various populations are as follows.

Patients with Decompensated Cirrhosis

Patients with decompensated cirrhosis, defined as CTP class B or C cirrhosis, are at high risk for developing complications of their end-stage liver disease and thus are recommended to be treated by clinicians with expertise in managing decompensated cirrhosis.[31] As a class, the protease inhibitors are not recommended in patients with decompensated cirrhosis due to the risk of further decompensation including liver failure. The only therapies recommended for use in decompensation include ledipasvir/sofosbuvir and sofosbuvir/velpatasvir.

Persons Who Inject Drugs

Injection drug use is not a contraindication to therapy and treatment of PWIDs will be necessary to reduce HCV transmission.[52] Treatment of PWIDs is recommended as part of a comprehensive harm-reduction effort, ideally in a multidisciplinary setting.[31,52] Treatment outcomes are comparable to rates in those in clinical trials among persons without injection drug use and reinfection rates among PWID are low.[53] However, access to HCV therapies is limited as many insurers refuse coverage of HCV therapies in the setting of active drug use.

Persons with Ongoing Alcohol Use

Alcohol cessation is recommended for all patients with liver disease. However, due to the short-treatment course, safety profile of the DAAs, and the ability to cure HCV, ongoing alcohol use is not a reason to withhold or defer HCV treatment.[31]

End-Stage Renal Disease

There are no dose adjustments needed for the DAAs in patients with chronic kidney disease including for patients on hemodialysis. In contrast, ribavirin elimination is dependent on renal function and significant dose adjustments may be necessary.

Patients with HCV GT3

In patients with HCV GT3 and cirrhosis, a more aggressive treatment strategy may be recommended due to the concerns for lower SVR rates in some patients. For patients who are to be treated using sofosbuvir/velpatasvir and who have cirrhosis or prior TE, pretreatment resistance testing is recommended.[31] If the Y93 mutation is identified, ribavirin should be added to the treatment course. Alternatively, a different regimen should be used, such as sofosbuvir/velpatasvir/voxilaprevir. In contrast, glecaprevir/pibrentasvir is recommended for an 8-week treatment course for patients with HCV GT3 and cirrhosis although the level of evidence to support the 8-week treatment duration in patients with cirrhosis is lower than the 12-week course.[31] As a result, some clinicians will prefer to use a 12-week course of glecaprevir/pibrentasvir in patients with cirrhosis and HCV GT3. Guidelines do recommend a 12-week treatment course for HIV-HCV coinfection in persons with cirrhosis and HCV GT3 infection.[31]

DAA-Experienced Patients

Patients without cirrhosis or those with compensated cirrhosis who failed any course of DAA therapy (eg, elbasvir/grazoprevir, glecaprevir/pibrentasvir) or any prior HCV regimen which included sofosbuvir can be retreated with sofosbuvir/velpatasvir/voxilaprevir. For patients with cirrhosis who were previously treated with glecaprevir/pibrentasvir and experienced treatment failure, the addition of ribavirin may be considered to sofosbuvir/velpatasvir/voxilaprevir. Glecaprevir/pibrentasvir is an alternative retreatment strategy; however its use is limited to specific patient populations and to specific prior treatment experience and requires an extended treatment duration of 16 weeks. For patients who failed multiple prior DAA therapies, including sofosbuvir/velpatasvir/voxilaprevir or the combination of sofosbuvir plus glecaprevir/pibrentasvir, there are limited options for retreatment. Using available therapies, the recommended retreatment in these unique circumstances includes the addition of ribavirin and retreatment for a longer duration of therapy.[31,51] There are no recommendations for pretreatment resistance testing in this population, and given the small number of patients who failed DAA therapy, it is difficult to predict who will fail DAA treatments.

HIV Coinfection

Patients with HIV HCV coinfection should be treated as having HCV monoinfection. Despite this, patients with HIV HCV coinfection are not candidates for the simplified algorithm. Similarly, the 8-week treatment duration is not recommended for patients with compensated cirrhosis and HCV and HIV coinfection. Potential drug–drug interaction concerns between HCV DAAs and HIV antivirals do merit careful scrutiny and may necessitate antiretroviral drug changes.[31] The University of Liverpool HCV drug interaction checker is a useful resource for up to date information on drug interactions.

Preferred HCV therapies for treatment-naïve patients with HIV coinfection are the pan-genotypic agents—sofosbuvir/velpatasvir or glecaprevir/pibrentasvir. Elbasvir/grazoprevir and ledipasvir/sofosbuvir may also be used. Sofosbuvir/velpatasvir has few clinically significant drug–drug interactions but should be avoided with efavirenz, etravirine, or nevirapine. Ledipasvir and velpatasvir increase tenofovir disoproxil levels and may increase the risk of tenofovir-associated renal toxicity especially if combined with cobicistat or ritonavir; however, this risk is minimized with tenofovir alafenamide and thus is the preferred formulation of tenofovir. Glecaprevir/pibrenasvir can be used in patients concurrently on abacavir, bictegravir, cabotegravir, dolutegravir, doravirine, emtricitabine, fostemsavir, ibalizumab-uiyk, lamivudine, maraviroc, raltegravir, rilpivirine, and tenfovir. Glecaprevir/pibrenasvir exposure can increase when combined with elvitegravir/cobicistat with a concern for potential resultant hepatic toxicity. Pending more data, concomitant use necessitates more frequent monitoring for worsening liver function. For patients who are DAA treatment experienced, sofosbuvir/velpatasvir/voxilaprevir is recommended.

HIV treatment poses additional problems because of hepatotoxicity issues associated with HAART, hepatic complications from HIV-associated diseases, as well as flares in hepatitis as CD4 counts recover. In general, treatment is recommended with coadministration of HIV and HCV therapies and is considered a priority due to more liver-related morbidity and mortality than in HCV mono-infected patients.

Children

Although the number of pediatric HCV cases is low, there are no good epidemiological studies to determine the actual prevalence of HCV in the pediatric population. Mother-to-child transmission is possible and of concern given the rise in HCV prevalence among younger females of childbearing age. Because maternal HCV antibody can persist and thus interfere with an infant's HCV antibody test, testing in newborns is not recommended until 18 months of age.[31] This delay in testing raises concerns for loss to follow up and potential missed opportunities for HCV diagnosis. Although fibrosis progression is generally considered slow in children, there is a general lack of data on the impact of persistent viremia on child development. Children with HCV as well as their families may face stigma and discrimination due to a general lack of knowledge about HCV and HCV transmission.

HCV DAA treatment is available; however is deferred until age 3 due to limited data in children. Both pan-genotypic agents are approved (sofosbuvir/velpatasvir and glecaprevir/pibrentasvir) as is ledipasvir/sofosbuvir. Pediatric dosing may be done with reduced dose tablets and pellets/granules which may be sprinkled over food.

Similar to adult clinical trial data, glecaprevir/pibrentasvir is highly effective in pediatric patients and is approved for children 3 years of age and older. The overall SVR was 96% in 80 children ranging in age from 3 to 12 years and with HCV GT1, 2, 3, or 4 infection.[54] The most common side effect was headache with patients also reporting vomiting and diarrhea. Glecaprevir/pibrentasvir is available as oral pellets for pediatric use.

Sofosbuvir/velpatasvir is also highly effective in pediatric patients and approved for children 3 years of age and older. SVR rates were 92% overall in 216 patients ranging in age from 3 to 17 years.[55] Virological failure was 1%, of the 17 patients who did not have a document SVR. The adverse effect profile was similar to what was observed in adult trials. Younger patients were more likely to report vomiting.

Ledipasvir/sofosbuvir is also an option and is available in a smaller dose tablet (45 mg/200 mg) as well as oral pellets (45 mg/200 mg or 33.75 mg/150 mg). The expected SVR is high at 98%.[56] The main limitation of this combination therapy is that it is not pan-genotypic; it is indicated for patients with HCV GT1, 4, 5, or 6.

Pregnancy

Transmission of HCV can occur during pregnancy and children born to mothers with HCV should be tested for HCV. HCV screening is recommended for each pregnancy; however, HCV therapy is not recommended during pregnancy.[31]

Post-Organ Transplant

Given the high efficacy of the DAAs and the number of HCV-positive organ donors, some organ transplant centers are offering HCV-positive organs to HCV-negative patients. Pan-genotypic agents are preferred in the transplant setting. Both glecaprevir/pibrentasvir and sofosbuvir/velpatasvir are recommended as soon as the patient is clinically stable but preferably within the first week after transplant. Experience in the transplant setting is increasing and includes liver, heart, lung, and kidney transplant.[31,57]

Prevention

No vaccine is available for HCV. It is unlikely that a vaccine will be developed in the near future because of the mutagenesis of the virus. Although the likelihood of household transmission is small, patients should minimize risks by avoiding possible blood or mucus exposure, such as not sharing razors or toothbrushes and covering open wounds. Sharing of any drug paraphernalia poses a risk of transmission. Where legally allowed, patients should be provided with resources for needle and syringe exchange programs.

Targeted HCV treatment in specific patient groups can reduce transmission and offer substantial public health benefits. Patients who achieve cure (SVR) cannot transmit virus, thus interrupting HCV transmission. Improved access to HCV DAA therapy and scale-up of treatment efforts is critical to prevention of new infections.

Treatment Interruptions

In real world settings, treatment interruptions occur for a number of reasons. It is important to minimize treatment interruptions and identify solutions to help patients be successful in obtaining refills in a timely manner. Disruptions in the treatment course can cause treatment failure. It is important to review the most current guidance available.[31] Patients who miss a week or less of therapy should restart treatment immediately and complete the originally scheduled treatment course. Patients who miss 8 or more days during the first month of treatment should continue DAA therapy and ideally also obtain an HCV RNA. If the HCV RNA is negative, the original treatment duration should be completed. In contrast, if the HCV RNA is positive or unable to be obtained, or if the patient has HCV GT3 infection or cirrhosis, DAA therapy should be extended by an additional 4 weeks.

If a patient misses 8 to 20 days of therapy after receiving at least the first month of treatment, DAA therapy should be restarted immediately and an HCV RNA checked. If the RNA is negative, the originally scheduled therapy should be continued or extended by 4 weeks if the patient has GT3 or cirrhosis. If the RNA is positive or not obtained, treatment should be stopped.

If patients experience a treatment interruption of more than 20 days, DAA therapy should be stopped. Although not common, it is possible that some patients may experience cure. The recommendation is to wait and recheck HCV RNA 12 weeks after the last known dose of medication was taken to assess for possible cure (SVR12).[31]

SELF-ASSESSMENT QUESTIONS

1. Which of the following is correct regarding viral hepatitis infections?

   A. Hepatitis A virus is transmitted through contaminated food, water, or ice and can cause acute or chronic infections.

   B. Hepatitis B virus is transmitted through blood, mucosal fluids, or contaminated food or water and can cause acute or chronic infections.

   C. Hepatitis C virus is transmitted through blood or contaminated food or water and can cause acute or chronic infections.

   D. Hepatitis B and C are transmitted through blood and can cause acute or chronic infections.

2. Which of the following patients is at risk for hepatitis A virus infection?

A. A 51-year-old male who received two doses of vaccine and is traveling to a high-end resort in a country with high rates of HAV

B. A 21-year-old female who received one dose of vaccine 4 weeks before a known HAV exposure

C. A 1-year-old child who received a dose of HAV vaccine 2 months before traveling to a country with high rates of HAV

D. An unvaccinated 49-year-old homeless male living in a homeless encampment

3. A 26-year-old female is worried about HAV because she ate at a restaurant implicated in a HAV outbreak. Her records indicate she received 2 doses of the hepatitis A vaccine as a child. Which of the following is the best action?

A. Serological tests are needed to assess her risk of HAV.

B. Immunoglobulin should be given to prevent symptoms of HAV.

C. No vaccine or immunoglobulin necessary now.

D. She should receive a booster shot of HAV vaccine now to stimulate her immune response.

4. The immunization records of a child indicate that the first dose of the hepatitis A vaccine was with one of the available single antigen products approximately 1 year ago. Which of the following is correct?

A. A second dose should be given today with any single antigen HAV vaccine to complete the series.

B. A dose should be given today but with the same single antigen HAV vaccine as was given previously to complete the series.

C. A dose should be given today but if with a different product than previously given, will require restarting the vaccine series.

D. A dose should be given today with any HAV vaccine and will require a second shot in 6 months to complete the series according to the schedule.

5. Which of the following Hepatitis B serological test results are consistent with successful vaccination?

A. HBsAg (+), anti-HBc (+), anti-HB (+)

B. HbsAg (+), anti-HBc (−), anti-HB (−)

C. HbsAg (−), anti-HBc (+), anti-HB (−)

D. HbsAg (−), anti-HBc (−), anti-HB (+)

6. A patient is scheduled to start rituximab. On routine labs, anti-HBs is negative, HBsAg is positive, and an HBV DNA is found to be 1,000 IU/mL (kIU/L). All other laboratories are within normal limits. Which of the following is correct?

A. The patient is at risk for HBV reactivation and requires vaccination prior to starting rituximab.

B. The patient is at risk for HBV reactivation and should be started on HBV therapy.

C. The patient should receive vaccination against HBV. Treatment for HBV is not necessary now.

D. The patient has HBV but treatment is not necessary because the patient's viral load is low and there is no diagnosis of cirrhosis.

7. Which of the following statements regarding HBV vaccination is correct?

A. The Engerix-B, Recombivax, and Heplisav-B vaccines are interchangeable.

B. Serological response to HBV vaccine is high even after a single dose of vaccine.

C. Engerix-B and Recombivax are given as two doses, given 6 months apart.

D. The Heplisav-B vaccine is given in as two doses, given 4 weeks apart.

8. Which of the following therapies are recommended for treatment of HBV?

A. Adefovir, tenofovir diprovoxil, or entecavir

B. Entecavir, adefovir, or lamivudine

C. Tenofovir diprovoxil, tenofovir alafenamide, or entecavir

D. Tenofovir alafenamide, adefovir, or entecavir

9. Which of the following therapies is recommended for use in pregnancy to prevent mother-to-child transmission of HBV?

A. Adefovir

B. Lamivudine

C. Telbivudine

D. Tenofovir diprovoxil

10. A patient is screened for HCV and found to be HCV antibody positive. What is the correct interpretation of this lab finding?

A. Acute HCV infection

B. Chronic HCV infection

C. Either current or prior HCV infection, requires further evaluation

D. Immune protected against HCV

11. Which of the following is recommended for treatment of chronic HCV in DAA experienced patients?

A. Glecaprevir/pibrentasvir

B. Sofosbuvir/velpatasvir

C. Ledipasvir/sofosbuvir

D. Sofosbuvir/velpatasvir/voxilaprevir

12. Which of the following therapies is indicated for treatment of HCV genotype 1, 4, 5, or 6 only?

A. Glecaprevir/pibrentasvir

B. Sofosbuvir/velpatasvir

C. Ledipasvir/sofosbuvir

D. Sofosbuvir/velpatasvir/voxilaprevir

13. Which of the following therapies is indicated for use in patients with chronic HCV and decompensated cirrhosis?

A. Glecaprevir/pibrentasvir

B. Elbasvir/grazoprevir

C. Sofosbuvir/velpatasvir

D. Sofosbuvir/velpatasvir/voxilaprevir

14. Which of the following is indicated for use in a patient who was previously treated with a treatment such as ombitasvir/paritaprevir/ritonavir plus dasabuvir?

A. Glecaprevir/pibrentasvir

B. Sofosbuvir/velpatasvir

C. Ledipasvir/sofosbuvir

D. Sofosbuvir/velpatasvir/voxilaprevir

15. Which of the following is correct regarding the treatment of HCV in patients with HIV?

A. Treatment is extended and is longer than in HCV monoinfected patients.

B. Treatment is limited because of substantial drug–drug interactions.

C. Treatment is the same as in HCV monoinfected patients.

D. Treatment includes agents with activity against HCV and HIV.

SELF ASSESSMENT QUESTION-ANSWERS

1. **D.** Hepatitis B and C are transmitted through blood and can cause acute or chronic infections. Hepatitis A is an acute infection only and is transmitted through contaminated food, water, or ice.

2. **D.** An unvaccinated 49-year-old homeless man living in a homeless encampment. Vaccination for HAV is highly effective even with one dose of vaccine as long as it is administered at least 2 weeks prior to exposure.

3. **C.** No vaccine or immunoglobulin necessary now. The HAV vaccine is highly effective and serological testing to prove vaccine efficacy is not routinely recommended. The use of immunoglobulin is limited and considers also the circumstances, age, and underlying health status of the exposed individual. Post-exposure prophylaxis with vaccine is recommended but for unvaccinated persons.

4. **A.** A second dose should be given today with any single antigen HAV vaccine to complete the series. Ideally the vaccine series is completed with the same vaccine; however, it is preferable to complete the series with any HAV vaccine so that optimal vaccine efficacy is achieved.

5. **D.** HBsAg (−), anti-HBc (−), anti-HBs (+). In a patient without prior exposure to HBV (anti-HBc [−]), successful vaccination results in a reactive (+) anti-HBs. Patients who have replicating HBV will have a reactive HBsAg.

6. **B.** The patient is at risk for HBV reactivation and should be started on HBV therapy. The patient already has replicating HBV (as identified by HBsAg reactivity and a quantifiable HBV DNA). The use of rituximab in this setting is expected to suppress immune activity and allow more robust HBV replication, thus necessitating HBV treatment for the duration of rituximab therapy. Since the patient already has HBV, vaccine will not be helpful.

7. **D.** The Heplisav-B vaccine is given in as two doses, given 4 weeks apart. Engerix-B and Recombivax share a similar adjuvant for vaccination; however, this is different to the one used in Heplisav-B, thus these vaccines are not recommended to be used interchangeably. Unlike the HAV vaccine, the HBV vaccine is less effective and requires the full dosing regimen to maximize response.

8. **C.** The standard of care is with entecavir, tenofovir disoproxil fumarate, and tenofovir alafenamide because these agents have a high barrier to HBV resistance.

9. **D.** Tenofovir disoproxil is preferred due to its high barrier to resistance in HBV and experience in use in pregnancy.

10. **C.** Either current or prior HCV infection, requires further evaluation. To confirm HCV infection, an HCV RNA must be checked and only patients who have a quantifiable HCV RNA have HCV infection. Patients can spontaneously clear HCV infection or undergo HCV treatment and achieve cure but will continue to have an HCV antibody detected.

11. **D.** Sofosbuvir/velpatasvir/voxilaprevir is indicated for patients who were previously treated and failed by other DAA agents.

12. **C.** Ledipasvir/sofosbuvir has efficacy for genotypes 1, 4, 5, and 6. It is not considered a pan-genotypic agent because it is not effective for genotypes 2 or 3.

13. **C.** Sofosbuvir/velpatasvir. DAA therapies which include a protease inhibitor (those agents ending in –previr) are not recommended in patients with decompensated cirrhosis due to concerns for exacerbating further liver injury.

14. **D.** Sofosbuvir/velpatasvir/voxilaprevir is used in patients with DAA treatment failure. The combination of ombitasvir/paritaprevir/ritonavir plus dasabuvir was an early DAA used for HCV therapy.

15. **C.** Treatment is the same as in HCV monoinfected patients. Although drug–drug interactions need to be assessed prior to starting HCV therapy, most current HIV HAART can be used with current DAAs. Unlike HBV therapy, HCV DAAs do not have activity against HIV.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 59: Celiac Disease

Priti N. Patel; Robert A. Mangione

KEY CONCEPTS

KEY CONCEPTS

①Celiac disease is a chronic, small intestinal immune-mediated enteropathy caused by intolerance to gluten found in wheat, barley, rye, and other foods when a genetically predisposed person is exposed to the environmental trigger, gluten.

②The prevalence of celiac disease is 0.7% in America and is increasing in prevalence worldwide.

③The integrity of the tissue junctions of the intestinal epithelium is compromised in patients with celiac disease; this enables gluten to reach the lamina propria. The presence of gluten in the lamina propria and an inherited combination of genes contribute to the heightened immune sensitivity to gluten that is found in patients with celiac disease.

④The classic presenting symptom is diarrhea, which may be accompanied by abdominal pain or discomfort; however, during the past decade diarrhea has been reported as the main presenting symptom of celiac disease in less than 50% of cases.

⑤Dermatitis herpetiformis is a skin manifestation of small intestinal immune-mediated enteropathy caused by exposure to dietary gluten.

⑥The frequency of diagnosis of patients with celiac disease has increased; however, the majority of patients with this condition remain undiagnosed.

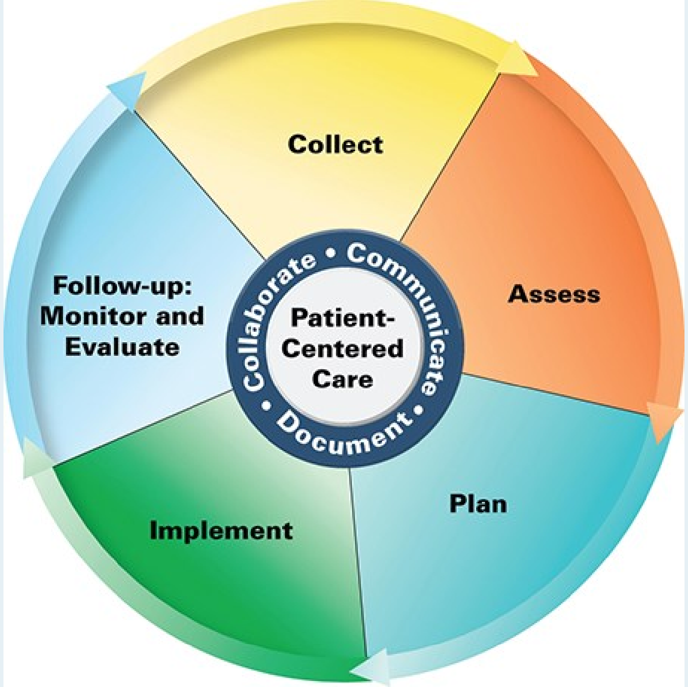
⑦The confirmation of a diagnosis of celiac disease should be based on a combination of findings from the medical history, physical examination, serology, and duodenal biopsy. The recommended serologic marker that is used for screening patients is serum antitissue transglutaminase antibody.

⑧Strict, lifelong adherence to a gluten-free diet is the only treatment for celiac disease that is available.

⑨Clinicians must evaluate the patient with celiac disease for nutritional deficiencies (including folic acid, vitamin B_{12}, fat-soluble vitamins, iron, and calcium) due to malabsorption.

PATIENT CARE PROCESS

Patient Care Process for Celiac Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, height, weight)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use) and dietary habits including intake of gluten-containing grains (see Table 59-1)
- Current medications including nonprescription, herbal products, dietary supplements
- Objective data
  - Results of diagnostic testing (HLA typing, serology, and/or biopsy)
  - Results of testing for nutritional deficiencies (eg, iron, folic acid, vitamin D, vitamin B_{12})
  - Results of other testing (eg, DEXA)

Assess

- Presence of signs and symptoms of malnutrition or nutrient deficiency
- Ability/willingness to follow gluten-free diet
- Ability/willingness to pay for treatment options (gluten-free food, dietary supplements)
- Emotional status (eg, presence of anxiety, depression)
- Family/caregiver support

Plan*

- Patient education (purpose of treatment, dietary and lifestyle modification)

- Self-monitoring for symptoms of celiac disease (intestinal and extra-intestinal)
- Referral to dietician
- Dietary supplement regimen including specific product(s), dose, route, frequency, and duration
- Medication regimen including identification of gluten-free oral medications

Implement

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, adherence assessment)

Follow-up: Monitor and Evaluate

- Resolution of celiac disease symptoms (eg, intestinal and extra-intestinal)
- Patient's adherence to treatment plan
- Resolution of nutritional deficiencies
- Repeat testing as needed (serology, biopsy, labs for nutritional deficiencies, DEXA)

**Collaborate with patients, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Read "Gluten in Medicine, Vitamins & Supplements" from the Celiac Disease Foundation at https://celiac.org/gluten-free-living/gluten-in-medicine-vitamins-and-supplements/. This provides a patient-centered guide for understanding the risks of gluten in medications and how patients with celiac disease may identify drugs that could pose problems for them. This is important information for pharmacists as well.

Read "Questions and Answers on the Gluten-Free Food Labeling Final Rule" from the Food and Drug Administration (FDA) at https://www.fda.gov/food/food-labeling-nutrition/questions-and-answers-gluten-free-food-labeling-final-rule. This question-and-answer format guide provides information on the FDA's gluten-free food-labeling regulation.

INTRODUCTION

① Celiac disease is a small intestinal immune-mediated enteropathy caused by intolerance to ingested gluten, a storage protein found in wheat, barley, and rye. Genetic, environmental, and immune factors all play a role in the development of celiac disease. The mainstay of treatment of the disease is strict, lifelong adherence to a gluten-free diet.[1]

A disease resembling celiac disease was first described by a Greek physician in the second century AD. In the mid-1900s, the connection between the ingestion of cereals and celiac disease was made. For many years, celiac disease was considered a disease of childhood with primarily gastrointestinal (GI) symptoms. It is now recognized as a disease of all ages with varied presentations.

Celiac disease has been known as celiac sprue, nontropical sprue, and gluten-sensitive enteropathy; however, these terms are not recommended. The nonspecific use of celiac disease-related terminology may lead to misunderstandings. Accepted terms associated with celiac disease should be used and understood when engaging in patient consultations or discussions with other healthcare providers. The publication of the Oslo Definitions of celiac disease helped to address this concern and further refining of appropriate terminology continues as new information is learned.[1] The Oslo classification used terminology such as "classic" and "non-classic" symptoms while more recent literature cites intestinal and extra-intestinal symptoms.[1]

The disease is characterized by both GI and extra-intestinal symptoms. Chronic inflammation caused by exposure to gluten leads to GI discomfort, nutrient malabsorption, and systemic complications. GI symptoms, including diarrhea, cramping, bloating, and flatulence, are the "classic" symptoms; however, a patient with celiac disease may initially present with a variety of extra-intestinal symptoms. Patients with subclinical celiac disease have no or minimal symptoms but manifest mucosal damage on biopsy and have positive serologic testing. Patients with celiac disease classified as potential are asymptomatic patients who may show positive serology and have the human leukocyte antigen (HLA)-DQ2 and/or DQ8 haplotype, but have normal mucosa on biopsy.[1,3]

Adherence to a gluten-free diet is essential because it improves symptoms and prevents long-term complications of celiac disease, which include T-cell lymphomas, small bowel adenocarcinoma, and esophageal and oropharyngeal carcinomas.[4]

EPIDEMIOLOGY

② Originally thought to be a pediatric disease, celiac disease is now being diagnosed in increasing numbers of both adult and pediatric patients due to increased awareness and improved diagnostic techniques.[5] Celiac disease is common in Europe and North America. The prevalence of the disease is 0.71% to 0.79% in the United States, affecting up to 1% of White patients.[6] The prevalence of celiac disease is higher in females than in males at a rate of1.5:1.[7] In Finland and the United States, the prevalence of celiac disease has increased fivefold during the past 50 years.[8]

Celiac disease has been less well studied in other parts of the world. Previously believed to rarely occur in racial groups other than White patients, improved screening and diagnostic techniques prove that the prevalence of celiac disease in many non-Western nations is similar to that in Europe and North America.[9] The common and increasing use of wheat in diets, coupled with the prevalence of HLA-DQ2, may lead to an increase in the prevalence of celiac disease in the global population in coming years in areas where celiac disease is rarely diagnosed.[10,11]

ETIOLOGY

Celiac disease is known to occur when a genetically predisposed person ingests gluten. Wheat gluten proteins exist in two fractions: gliadins and glutenins. Wheat, barley, and rye are all derived from the Triticeae tribe of the grass (Gramineae) family. Proteins similar to glutenins, called hordeins and secalins, are found in barley and rye, respectively. Table 59-1 refers to grains and other foods that do and do not contain gluten and related proteins. Ingestion of any of these proteins will lead to an autoimmune response in patients with celiac disease. Oats, from the Aveneae tribe, are distantly related and therefore contain fewer disease-activating proteins.[13] One concern with oats is that they may be contaminated with gluten during the manufacturing process.[13]

TABLE 59-1

Grains and Other Foods that Do and Do Not Contain Gluten

Contain Gluten	Do Not Contain Gluten
Wheat	Amaranth
Barley	Buckwheat
Rye	Corn
Bran	Flax
Graham flour	Millet
Spelt	Potato flour
Wheat germ	Quinoa
Triticale	Rice
Oats[a]	Sorghum
	Soybeans
	Tapioca
	Teff

[a] Oats are in a different plant family, but they have also been regarded as problematic, although the ingestion of certified pure gluten-free oats is safe in most patients with celiac disease.[12] Due to the continued difference of opinion regarding the safety of oats, patients are generally advised to discuss the risks and benefits associated with consuming oats with their healthcare provider before they include oats in their diet.

Genetic factors, in combination with exposure to gluten, are necessary for the development of celiac disease. There is a concordance rate of 85% in monozygotic twins indicating that genetics play a large role in the disease, but other factors also are likely to involved.[13,15]

Most patients with celiac disease have variants of HLA-DQ2 or HLA-DQ8 molecules that are expressed on the surface of antigen-presenting cells.[3,4] Other non-HLA genes may also play a role in enhancing genetic susceptibility to celiac disease.[16]

Various infections and compounds may contribute to the development of celiac disease. There is an association between change in the gut microbiome and celiac disease; however, experts caution against suggesting that the gut microbiome causes celiac disease since many environmental factors that play a role in celiac disease also affect the gut microbiome.[1,17] GI, upper respiratory, and lower respiratory infections are risk factors for the development of celiac disease. Various drugs, such as olmesartan, azathioprine, methotrexate, as well as others, may play a role in the development of sprue-like bowel disease.[2]

In Sweden, increased rates of diagnosis of celiac disease in the mid-1980s was thought to correspond to a change in infant feeding practices. However, the timing of gluten introduction or duration of breastfeeding did not avoid the eventual diagnosis of celiac disease, even at children at higher risk due to the presence of one of the high-risk HLA haplotypes.[16]

PATHOPHYSIOLOGY

③ During normal digestion, peptides that remain from gastric or pancreatic digestion are broken down into amino acids, dipeptides, or tripeptides by the small intestinal brush-border membrane enzymes.[16] These GI proteases that are found in the intestinal lumen are one of the body's first defenses against potentially toxic dietary proteins.[18] The intestinal epithelium, with its intact intercellular tight junctions, functions as the primary barrier to the passage of macromolecules into the lamina propria. Gluten is unusually rich in the amino acids glutamine and proline, which enable part of the molecule to withstand the digestive processes. These peptides are kept within the GI tract and are primarily excreted before they can illicit an immune reaction. Small fractions of gluten do cross this important defense barrier in patients without celiac disease; however, the quantity of gluten that passes across the GI lining is generally insufficient to illicit a significant response from a normally functioning immune system.[18]

Pathophysiology of celiac disease is associated with an interaction between gluten and immune, genetic, and environmental factors.[18] In celiac disease, the integrity of the tissue junctions of the intestinal epithelium is compromised, enabling gluten to reach the lamina propria through different routes. The presence of gluten in the lamina propria and an inherited combination of genes contribute to the heightened immune sensitivity to gluten found in patients with celiac disease (Table 59-2).[18] The notable immune response to gluten consists of both adaptive and innate immune responses that occur only in individuals who carry the HLA type DQ2 or DQ8.[18] The precise mechanism by which the immune system leads to damage of the intestinal lining of patients with celiac disease continues to be studied.

TABLE 59-2

Proposed Pathophysiology of Celiac Disease

- Enterocytes release the protein zonulin in response to the presence of indigestible fragments of gluten in the intestine.
- Zonulin loosens the intercellular tight junctions.
- Abundant quantities of gluten fragments cross the intestinal lining and accumulate under the enterocytes (epithelial cells).
- Gluten induces the enterocytes to secrete interleukin-15 (IL-15).
- IL-15 induces an immune response of intraepithelial lymphocytes against the enterocytes
- The damaged cells release the enzyme tissue transglutaminase (tTG), which modifies the gluten
- Antigen-presenting cells of the immune system join the modified gluten to HLA molecules and display the resulting complexes to other immune cells (ie, helper T cells).
- Helper T cells that recognize the complexes secrete molecules that attract other immune cells, which may result in damage to the enterocytes.
- Helper T cells spur killer T cells that directly attack the enterocytes.
- B cells release antibody molecules that are targeted to gluten and tTG (the role that these antibodies play remains to be further clarified; however, they may cause further damage when they contact their targets on or near the enterocytes).
- Enterocytes are disabled or killed.

Data from Reference 18.

Nonceliac gluten sensitivity is a condition in which the ingestion of gluten results in morphological or symptomatic manifestations in the absence of celiac disease.[19] This disorder must therefore be considered in the differential diagnosis of celiac disease. Symptoms alone cannot reliably differentiate celiac disease from nonceliac gluten sensitivity. Therefore, a diagnostic evaluation including celiac serology and small-intestinal biopsy (while the patient is including gluten in their diet) is needed. If these tests are negative, HLA-DQ typing is required to differentiate between the two disorders. Differentiating between these disorders is important as it will impact the implications of the level of adherence to the gluten-free diet, approach to continued disease-state monitoring and evaluation, and the counseling of family members (as nonceliac disease sensitivity does not have a strong hereditary basis).[4]

The primary toxic components of wheat gluten are a family of closely related proteins called gliadins.[18] The gliadin peptides induce changes in the epithelium through innate immunity and in the lamina propria through adaptive immunity.[18]

Tissue transglutaminase (tTG), a ubiquitous enzyme that catalyzes posttranslational modification of proteins and is released during inflammation, may play at least two crucial roles in celiac disease by serving as the main target autoantigen for antiendomysial enzymes and as a deaminating enzyme that raises the immunostimulatory effect of gluten. This enzyme, by deaminating glutamine to glutamic acid, makes the gliadin peptides become negatively charged and therefore more capable of fitting into pockets of the HLA-DQ2 (or HLA-DQ8) antigen-binding groove on the antigen-presenting cells.[21] Gliadin is presented to gliadin-reactive CD4 T cells through a T-cell receptor, which then results in the production of cytokines that cause tissue damage. This then leads to villous atrophy, crypt hyperplasia, and the expansion of antibody-producing B cells found in celiac disease.[21]

CLINICAL PRESENTATION

④ The recognition of celiac disease may be quite challenging due to the wide range of presenting symptoms, which includes patients who are asymptomatic.[1] Clinical manifestations of celiac disease significantly vary with age group (Table 59-3) in that pediatric patients are more likely to experience classic GI symptoms while adults are more likely to have extra-intestinal symptoms.[2] Infants and young children generally experience diarrhea, abdominal distention, and failure to thrive. Vomiting, irritability, anorexia, and even constipation are also common in these young patients. Extra-intestinal manifestations such as short stature, neurologic findings (eg, peripheral neuropathy, ataxia, seizure, migraine, and dementia), or anemia are often found in older children and adolescents.[23] The classic presenting symptom in adults is diarrhea, which may be accompanied by abdominal pain or discomfort; however, during the past decade diarrhea has been reported as the main presenting symptom of celiac disease in less than 50% of cases.[19,20] Adults may exhibit iron-deficiency anemia or osteoporosis. Less common presentations of celiac disease in adults include abdominal pain, constipation, weight loss, neurologic symptoms, dermatitis herpetiformis, hypoproteinemia, hypocalcemia, and elevated liver enzymes. Patients with celiac disease without GI symptoms often experience symptoms for a long period of time before celiac disease is diagnosed.[24]

TABLE 59-3

Selected Signs and Symptoms of Celiac Disease

Children	Adults
Symptoms - Fatigue - Bloating - Constipation - Abdominal pain - Chronic diarrhea - Irritability - Vomiting	Symptoms - Abdominal pain - Chronic diarrhea - Abdominal distension - Recurrent spontaneous abortion - Peripheral neuropathy - Depression - Fatigue/malaise - Ataxia
Signs - Muscle wasting - Failure to thrive/weight loss - Short stature - Delayed puberty - Osteopenia/osteoporosis - Hepatitis - Dental anomalies - Anemia	Signs - Weight loss - Infertility - Dermatitis herpetiformis - Hepatitis - Anemia - Aphthous ulcers - Alopecia - Malignancy - Seizures - Osteopenia/osteoporosis - Arthritis

Data from Reference 22.

⑤ Dermatitis herpetiformis is a skin manifestation of small intestinal immune-mediated enteropathy caused by the ingestion of gluten.[25] This extremely pruritic, bullous skin rash should prompt testing for celiac disease.[25]

⑥ The diagnosis of celiac disease is based on clinical suspicion and confirmation with laboratory tests and duodenal biopsy.[4] Although the prevalence of celiac disease has increased, many patients with this condition remain undiagnosed.[4] This is particularly concerning as undiagnosed celiac disease has been associated with a nearly fourfold increased risk of death compared with subjects without serologic evidence of disease.[12]

Healthcare providers should recognize the many and diverse possible symptoms of celiac disease.[19] A delay in diagnosis is often reported, with longer times to diagnosis in patients who primarily exhibit extra-intestinal symptoms.[24] Clinicians can help reduce the time from the onset of symptoms to the diagnosis of celiac disease by being aware of the common diseases that may also coexist with celiac disease (Table 59-4).[24]

TABLE 59-4

Selected Common Misdiagnoses

- Irritable bowel syndrome
- Viral gastroenteritis
- Lactose intolerance
- Amoebic/parasitic infection
- Inflammatory bowel disease
- Psychological dysfunction
- Gallbladder disease
- Chronic fatigue syndrome
- Gastroesophageal reflux disease
- Allergies
- Ulcers
- Cystic fibrosis
- Colitis

Data from Reference 4.

Individuals with certain disorders are more likely to have celiac disease than the general population. Examples include other autoimmune diseases, such as thyroid disease, diabetes mellitus (type 1), multiple sclerosis, myasthenia gravis, Raynaud's disease, rheumatoid arthritis, Addison's disease, chronic active hepatitis, cystic fibrosis, scleroderma, and Sjögren's syndrome; Down's syndrome; neurologic conditions such as ataxia, epilepsy, and cerebral calcifications; and primary biliary cirrhosis. Although patients with these disorders are more frequently found to have celiac disease than the general population, these associated conditions are not believed to cause celiac disease.[26]

⑦ Diagnostic testing for celiac disease must be performed while the patient continues to consume gluten; patients who have already started on a gluten-free diet prior to diagnosis should consume three slices of wheat bread daily for 1 to 3 months before testing commences.[5,27] A confirmed diagnosis of celiac disease requires both a positive finding on duodenal biopsy and a positive response to a gluten-free diet.[4] The identification of villous atrophy with small bowel endoscopy and biopsy is generally regarded as the diagnostic gold standard (although according to the guidelines from the European Society of Paediatric Gastroenterology, Hepatology, and Nutrition a small intestinal biopsy may not be required in children with typical symptoms, titers of anti-tTG greater than 10 times the upper normal limit and predisposing HLA genotype).[28] Although villous atrophy is associated with celiac disease, clinicians must consider that this may also be found in other diseases, including giardiasis, autoimmune enteropathy, tuberculosis, Crohn's disease, intolerance to food other than gluten, intestinal lymphoma, and Zollinger–Ellison syndrome.[4]

Histologic changes seen on biopsy are categorized according to one of several classification systems including the Marsh, Marsh modified, or the Corazza, all of which examine intraepithelial lymphocytes, crypt hyperplasia and villous atrophy.[4] Histologic findings lead to a diagnosis that is followed by placing the patient on a gluten-free diet. Dermatitis herpetiformis is diagnosed by skin biopsy.[29]

Serologic test results provide clinicians with a useful noninvasive tool that helps to determine if symptomatic patients, or patients who are at risk for celiac disease, require a biopsy.[4] Available tests include those for deamidated gliadin peptide (DGP) IgA or IgG antibodies, anti-endomysial antibodies, and antibodies against tTG. The American College of Gastroenterology recommends tTG IgA testing for patients 2 years and older and DGP IgA and IgG combined with IgA tTG for patients younger than 2 years.[4] Although serology is a good method to identify patients who will benefit from endoscopy and biopsy, negative serology should not preclude a biopsy examination in individuals for whom disease is suspected on clinical grounds.[4] Positive serology should be followed with confirmatory testing via biopsy, with the exception of some children who may be diagnosed based on serology alone.[4,28]

Genetic testing can be performed as a means of determining which family members of a diagnosed patient may develop the disease (the prevalence of celiac disease is 10% to 12% in first-degree relatives and is also higher than that found in the general population in second-degree relatives).[4] Patients and their family members can be tested for HLA-DQ2 and HLA-DQ8 as HLA-DQ2 is found in up to 95% of patients with celiac disease, with most other patients being HLA-DQ8 positive.[4] Although nearly all patients with celiac disease carry one of these alleles, they are also found in 30% to 40% of the general population. When these alleles are absent, it is extremely unlikely that the individual has celiac disease (ie, the test has a high negative predictive value).[4] A patient-administered saliva-based test for HLA-DQ2/DQ8 was released for direct sale to consumers but is not recommended for use in the diagnosis of celiac disease.[4]

In 2017, the US Preventive Services Taskforce stated that the evidence on hand is “insufficient to assess the balance and harms of screening for celiac disease in asymptomatic persons.”[30]

Forms of celiac disease that have been identified in practice since the publication of the Oslo classification include seronegative celiac disease, in which a patient experiences symptoms and positive findings in biopsy but is negative for serum markers, and gluten-free diet-nonresponsive celiac disease, in which a patient does not respond to 12 months of strict gluten-free diet.[2] Potential celiac disease is an additional new term indicating the presence of serum antibodies and HLA-DQ2/8 but normal intestinal mucosa.[31]

TREATMENT

Desired Outcomes

The main goals of treatment include relieving symptoms, healing the intestine, and prevent complications. In children, increases in height and weight are additional goals.[27]

General Approach to Treatment

The mainstay of treatment of celiac disease is the strict, lifelong adherence to the gluten-free diet. Supportive care of nutrient deficiencies should be addressed through drug therapy and preventive care, such as vaccines, should be recommended.

Nonpharmacologic

⑧ Table 59-5 presents a mnemonic that summarizes the major principles of the treatment of celiac disease. Strict lifelong adherence to a gluten-free diet is the only proven treatment for celiac disease.[1] Patients must recognize that adhering to a gluten-free diet includes not ingesting anything that contains gluten or has been contaminated with gluten. Wheat, barley, and rye must be avoided.[3] Although oats are in a different plant family, they may be problematic; however, the ingestion of certified pure gluten-free oats is safe.[25] Due to the continued difference of opinion regarding the safety of oats, they should be added to the diet cautiously and with monitoring.[4] Patients must also commit to avoiding the ingestion of gluten found in nonfood items such as toothpaste, lip balm, lipstick, etc.[12] A list of gluten-free grains can be found in Table 59-1.

A	Access to an advocacy group
C	Continuous long-term follow-up by a multidisciplinary team

Data from Reference 32.

Oral prescription drugs, nonprescription drugs, vitamin and mineral supplements, and health and beauty aids and cosmetics that have oral ingestion potential must not be overlooked as sources of gluten due to its presence in their formulation or due to contamination or contact.[12] Lack of reliable information can be confusing and although there are published lists of gluten-free drugs, it is often difficult to obtain information about the gluten content of medications.[33] Patients with celiac disease are concerned about the possibility of gluten in medications causing disease-related symptoms.[34] Also, the FDA issued draft guidance on “Gluten in Drug Products and Associated Label Recommendations” encouraging drug manufacturers to have accurate information about their products’ gluten content available so they can respond to questions from consumers. Healthcare professionals and some researchers have advocated that all medications should be gluten-free.[35] Clinicians should realize that conflicting data regarding drug absorption requires careful selection and use of drugs in patients with celiac disease.[36]

The FDA determined the tolerable daily intake level for gluten in individuals with celiac disease to be 0.4 mg gluten/day for adverse morphologic effects and 0.015 mg gluten/day for adverse clinical effects and ruled that foods labeled on or after August 5, 2014 as gluten-free must contain less than 20 ppm gluten.[37,38] Although the ruling pertains to food only, the concerns regarding low-level exposure emphasize why healthcare providers must check to determine whether prescription drugs contain gluten in their formulation or have been contaminated with gluten before these drugs are provided to the patient with celiac disease.

⑨ Newly diagnosed patients should be evaluated for nutritional deficiencies associated with vitamin and mineral malabsorption, including folic acid, vitamin B_{12}, fat-soluble vitamins, iron, and calcium.[4] Monitoring for potential nutritional deficiencies should also continue during subsequent follow-up visits.

Most adults with celiac disease have some degree of bone loss. Therefore, all patients must be screened for osteoporosis or osteopenia.[39,40] Supplementing a gluten-free diet with calcium, magnesium, and vitamin D may arrest or reverse celiac-related bone loss. Although their use has not been extensively studied in patients with celiac disease, bisphosphonates and other drugs have been prescribed for patients with bone disease.[36]

Implementing a gluten-free diet presents some challenges. Consultation with a registered dietician is recommended for dietary evaluation and education.[4] Patients are advised to initiate a complete gluten-free lifestyle immediately after diagnosis. Partial adherence to this diet is not adequate. In order to accomplish this objective, patients must be aware of what foods are gluten-free and when in doubt must know how to confirm whether a food contains gluten. Reading labels is extremely important; however, it may be difficult to identify hidden sources of gluten listed among the ingredients. Patients with celiac disease must also determine whether products were processed on equipment shared with wheat, barley, or rye. It may be necessary to call the manufacturers or check their website to obtain the needed information.[41] Patients should seek guidance from a dietitian in order to avoid incurring nutritional deficiencies such as with fiber, vitamins and minerals, or overconsumption of fats, both of which can occur with gluten-free diets.[1]

Individuals with celiac disease must also be advised to maintain a gluten-free kitchen. A dedicated toaster, bread maker, waffle iron, and other appliances should be obtained for use in preparing gluten-free meals. Utensils and dishes must be carefully cleaned to avoid gluten contamination. Care must also be taken when dining in restaurants and homes of family and friends. The individuals who prepare and serve the food must be knowledgeable about gluten-free foods and food preparation.[12] The economic burden associated with maintaining a gluten-free diet may present some challenges.[42] The relatively low availability and high cost of these foods contribute to the challenges associated with adhering to the required strict diet and may lead to varying degrees of noncompliance.[43,44] Patients also find that the extra cost associated with the special diet is not reimbursed by healthcare plans, and most policies do not pay for consultations with a dietician.[44] These challenges with compliance are particularly concerning as noncompliance with the gluten-free diet is associated with an increased mortality rate and compromised quality of life.[43] Hypervigilance to a strict gluten-free diet may negatively impact upon the patient’s quality of life and clinicians should therefore also promote the social and emotional well-being of the patient while counseling about the importance of adhering to the gluten-free diet.[45] Patients are also encouraged to investigate their personal circumstances as to whether some of the costs of maintaining a gluten-free diet are eligible for approval as a tax deduction.[44]

Pharmacologic

Dietary avoidance of gluten remains the mainstay of treatment of celiac disease. Novel pharmacologic treatment modalities are under investigation. Most reports related to pharmacotherapy for celiac disease focus on the treatment of refractory disease.

In case reports, corticosteroids, azathioprine, cyclosporine, tacrolimus, infliximab, and alemtuzumab have been reported as effective treatments for refractory celiac disease. Patients characterized to have refractory celiac disease have persistent or recurrent malabsorptive symptoms and signs with villous atrophy despite maintaining a gluten-free diet for more than 12 months.[1] Less than 5% of adult patients have refractory celiac disease.

Based on the pathophysiology of celiac disease, novel targets for the treatment of the disease have been identified: decreasing the antigenic load and modulation of the immune response. Methods of decreasing the antigenic load include blocking the activity of tTG, GI destruction of proline peptides via enzyme therapy, blocking the binding of deaminated proteins to HLA-DQ2 and HLA-DQ8, detoxification of gluten peptides, and decreasing intestinal permeability in patients with celiac disease, in particular through inhibition of zonulin.[2] A zonulin inhibitor, larazotide, was well tolerated and had efficacy in three phase-2 studies, allowing patients to tolerate small amounts of gluten through symptom control in patients who did not respond fully to a gluten-free diet.[1,47] Latiglutenase is a combination of recombinant proteases which aims to digest small amounts of gluten.[1]

EVALUATION OF THERAPEUTIC OUTCOMES

Clinical improvement will often be observed within days or weeks of instituting a strict gluten-free diet.[47] Repeat biopsy may be a helpful tool to monitor mucosal healing, particularly in patients with ongoing symptoms.[1,27]

Healthcare providers must also be mindful of conditions that are related to celiac disease and that are potential complications of the disease, including certain forms of cancer, neurologic manifestations, osteoporosis, depression, diabetes, infertility, as well as other autoimmune and related illnesses. Cancers that are of particular concern include thyroid cancer, adenocarcinoma of the small intestine, lymphoma (predominantly non-Hodgkin's lymphoma of any type), esophageal cancer, melanoma, and malignancies found in childhood.[3] Patients with celiac disease have an increased risk of developing certain infectious diseases, including pneumococcal infection.[48] Therefore, the pneumococcal vaccine should be recommended for all age groups, especially for those patients who did not receive the vaccine as a child.[48] Annual influenza vaccine is advisable as this will reduce the incidence of secondary bacterial infections.[49]

SELF-ASSESSMENT QUESTIONS

1. Which of the following grains contains gluten?

A. Sorghum

B. Buckwheat

C. Bran

D. Amaranth

2. Which drugs have been reported to play a role in the development of a sprue-like bowel disease?

A. Omeprazole

B. Olmesartan

C. Omalizumab

D. Octreotide

3. Regarding the role of breastfeeding and the risk of celiac disease, what is an appropriate recommendation?

A. Avoiding breastfeeding can delay the onset of celiac disease

B. Delaying the cessation of breastfeeding can avoid the onset of celiac disease

C. Early introduction of gluten during breastfeeding delayed the onset of celiac disease

D. The timing of gluten introduction in relation to breastfeeding does not avoid the eventual diagnosis of celiac disease

4. In active celiac disease, damaged cells release which enzyme that modifies gluten?

A. Interleukin-15

B. Tissue transglutaminase

C. Pancrease

D. Pepsin

5. Which symptom of celiac disease may appear more commonly in children than in adults?

A. Vomiting

B. Fatigue

C. Abdominal pain

D. Diarrhea

6. When should diagnostic measures occur?

A. Before a gluten-free diet is initiated

B. At the same time that a gluten-free diet is initiated

C. After a gluten-free diet is initiated

D. With no consideration to timing of initiation of a gluten-free diet

7. Which of the following disorders is more likely to be present in individuals with celiac disease?

A. Asthma

B. Cardiac hyperplasia

C. Dyslipidemia

D. Diabetes mellitus

8. A 45-year-old male patient with chronic diarrhea and a 10-lb (4.5 kg) weight loss over 3 months is tested for HLA-DQ2. The test is positive. Which of the following statements is correct?

A. The patient is confirmed to have celiac disease based on this serology test.

B. Based on this serology test, the patient does not have celiac disease.

C. The patient must undergo endoscopy with biopsy to confirm the diagnosis of celiac disease.

D. The test is inconclusive as the patient should have been tested for HLA-DQ8 as that is more common.

9. A patient is confirmed to have celiac disease after a positive biopsy. His two teenage sons wish to know if they are at risk for celiac disease as well. Which of the following tests can be used to his sons for celiac disease?

A. CD4 count

B. Antigliadin antibodies

C. Tissue transglutaminase

D. HLA DQ2 and DQ8

10. Which of the following nutritional deficiencies needs to be assessed in newly diagnosed patients with celiac disease?

A. Vitamin C

B. Zinc

C. Iron

D. Selenium

11. Within what period of time is clinical improvement often observed in patients with celiac disease after initiating a strict gluten-free diet?

A. Within days or weeks

B. 6 months to 1 year

C. 1 to 2 years

D. 2 to 3 years

12. What did the Food and Drug Administration (FDA) rule in 2014 in relation to gluten?

A. Foods labeled as gluten-free must contain less than 20 ppm gluten.

B. Both foods and drugs labeled gluten-free must contain less than 20 ppm gluten.

C. Drugs labeled gluten free must contain less than 20 ppm gluten.

D. The FDA issued a warning in 2014 and will revisit the issue in 2020.

13. A 13-year-old girl with celiac disease is being counseled on avoiding nonfood sources of gluten. Which of the following personal care items should they be warned of?

A. Shampoo

B. Body lotion

C. Nail polish

D. Lipstick

14. Which of the following recommendations is appropriate for patients with celiac disease?

A. They should be screened for dyslipidemia annually.

B. Patients of all ages should receive the pneumococcal vaccine.

C. They must only use topical products that are gluten-free.

D. All patients should undergo a skin biopsy to detect dermatitis.

15. A novel drug in development for the treatment of celiac disease, larazotide, targets which of the following?

A. Tissue transglutaminase

B. HLA-DQ2

C. Proline peptides

D. Zonulin

SELF-ASSESSMENT QUESTIONS ANSWER

1. **C.** Bran is a gluten-containing grain.
2. **B.** There are numerous reports in the published literature of olmesartan causing a sprue-like bowel disease.
3. **D.** While earlier reports supported the idea of introducing gluten during breastfeeding during a specific “window” between 4 and 6 months of age to minimize the risk of celiac disease, this does not seem to be the case based on newer studies. The timing of gluten introduction does not affect the risk of eventual celiac disease diagnosis.
4. **B.** Tissue transglutaminase is the enzyme that modifies gluten.
5. **A.** Vomiting is a symptom that may be seen more commonly in children than in adults.
6. **A.** The diagnosis of celiac disease should occur before a gluten-free diet is initiated; that is, while gluten is still being consumed.
7. **D.** Diabetes mellitus is more likely to be present in patients with celiac disease.
8. **C.** A positive serology test must be confirmed by a biopsy to properly diagnose celiac disease. A negative serology test can effectively rule out celiac disease, unless a patient’s symptoms warrant further investigation via endoscopy.
9. **D.** Family members can be screened for celiac disease using the serology tests HLA-DQ2 and HLA-DQ8. Negative tests for both of these can effectively rule out celiac disease in the absence of symptoms.
10. **C.** Calcium, vitamin D, and iron all need to be assessed upon diagnosis and addressed appropriately. Zinc, vitamin C, and selenium are less common nutritional deficiencies in celiac disease and do not need to be assessed upon diagnosis.
11. **A.** Clinical improvement can be seen in a patient with celiac disease days to weeks after instituting a gluten-free diet.
12. **A.** The FDA ruled that foods labeled on or after August 5, 2014 as gluten-free must contain less than 20 ppm gluten.
13. **D.** Gluten can be ingested orally through lipstick.
14. **B.** It is recommended for patients with celiac disease of all ages to receive the pneumococcal vaccine, particularly if they did not receive the vaccine as a child.
15. **D.** Larazotide is a zonulin inhibitor.

Chapter 61: Acute Kidney Injury

Jenana Maker; Lauren Roller; William Dager

KEY CONCEPTS

KEY CONCEPTS

① Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines provides a classification system for diagnosing and staging acute kidney injury (AKI). This classification system is based on separate criteria for serum creatinine (S_{cr}) and urine output.

② AKI is a common complication in critically ill patients that is different than chronic kidney disease and is associated with high morbidity and mortality.

③ AKI is typically categorized based on three types of injury: (a) prerenal—decreased renal blood flow, (b) intrinsic—structural damage within the kidney, and (c) postrenal—an obstruction within the urine collection system.

④ Serum creatinine, urea, and urine output are commonly used markers of kidney function in clinical practice. However, advances in AKI research have led to the development of multiple novel biomarkers that can be used for risk assessment, early detection, classification, and prognosis in AKI.

⑤ Conventional formulas used to estimate glomerular filtration rate (eGFR) are not recommended in AKI patients. In addition, medication dose adjustment recommendations are typically based on limited pharmacokinetic studies conducted in chronic kidney disease (CKD) patients and may not be reflective of pharmacokinetic changes and dosing requirements in AKI patients.

⑥ The most effective prevention strategies for AKI include limiting exposure to nephrotoxic medications and optimizing the patient's hemodynamic and fluid status. Incorporation of electronic health alerts may increase early detection and decrease risk of AKI progression.

⑦ Supportive management remains the primary approach to prevent or reduce complications associated with AKI or comorbid conditions. Supportive therapies include renal replacement therapy (RRT), nutritional support, identifying potential causes and avoidance of nephrotoxins, blood pressure management, and fluid management.

⑧ For patients with prolonged or severe AKI, RRT is the cornerstone of support along with aggressive fluid and electrolyte management.

⑨ Medication dosing for AKI patients receiving continuous renal replacement therapy (CRRT) or prolonged RRT is poorly characterized. Dosing requirements of agents primarily eliminated by the kidney may require individualization and may be higher than observed in CKD. Dosing requirements may need to be adjustment downward as kidney function declines, and then subsequently increase as AKI resolves. Therapeutic drug monitoring should be utilized whenever possible for any agent with a narrow therapeutic index.

PATIENT CARE PROCESS

Patient Care Process for Acute Kidney Injury

Collect

- Patient characteristics (eg, age, sex)
- Chief complaint/reason for admission
- Patient medical history including other relate co-morbid conditions (eg, CKD, diabetes, HTN, cirrhosis)
- Current medication list
- Baseline serum creatinine (if available)
- Volume status (low fluid volume eg, dehydration), urine output
- Hemodynamic (eg, blood pressure, mean arterial pressure)
- Urinalysis results (eg, WBCs, RBCs, protein, granular casts, FE_{Na}) (see Table 61-2)
- Kidney imaging results (eg, obstruction, hydronephrosis)

Assess

- Stage and severity of AKI using KDIGO criteria (Table 61-1)
- Most likely type of AKI (Fig. 61-2)
- Presence of baseline CKD
- Presence of sepsis, severe sepsis, or septic shock
- Presence of electrolyte disturbances
- RRT modality and parameters if applicable (Fig. 61-3)

Plan*

- Assess direction and degree of changing kidney function
- Review all medications for appropriateness and ensure doses and frequencies are adjusted for patient’s current kidney function and RRT
- Evaluate presence and eliminate any potential nephrotoxins
- Need for electrolyte corrections
- Identify any renally eliminated medications with narrow therapeutic indexes. Recommend therapeutic drug monitoring when necessary.

Implement*

- Formulate a management plan for any necessary medication additions, deletions or dose alterations
- Communicate treatment plant to the patient’s primary team and nephrology team (if consulted)
- Document therapy recommendations including dose adjustments and follow-up assessment plans in the patient’s electronic health record or chart
- Provide patient education regarding all elements of treatment plan (when possible)

Follow-up: Monitor and Evaluate (Table 61-7)

- Changes in kidney function (eg, changes in S_{cr}, urine output, continued need for RRT or changes in the RRT approach)
- Hemodynamic and volume status
- Electrolytes, acid-base status
- Response to the medication regimen including any potential adverse events
- Patient adherence to treatment plan using multiple sources of information
- Overall clinical status and management progression

[*] *Collaborate with patient, caregivers, and other healthcare professionals*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled "Changing Glomerular Filtration Rate" in Khan Academy (https://youtu.be/x0pFo1RxTzM). This 4 min video provides a brief overview of how changes in afferent and efferent arteriolar tone control the glomerular filtration rate. This video is useful to enhance student understanding of the pathophysiology and medication-induced causes of AKI, as well as the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

Acute kidney injury (AKI) is a clinical syndrome generally defined by an abrupt reduction in kidney function as evidenced by changes in serum creatinine (S_{cr}), blood urea nitrogen (BUN), and urine output. The consequences of AKI can be serious, especially in hospitalized patients. Early recognition along with supportive therapy is the focus of management for those with established AKI, as there is no pharmacologic therapy that directly reverses the injury. Individuals at risk, such as those with history of chronic kidney disease (CKD), need to have their hemodynamic status carefully monitored and their exposure to nephrotoxins minimized. A thorough patient assessment including medical and surgical history, medication use, physical examination, and multiple laboratory tests is essential. Management goals include maintenance of blood pressure, fluid and electrolyte homeostasis, all of which may be dramatically altered in the presence of AKI, as well as the use of diuretics and renal support therapies. Additional therapies designed to eliminate or minimize the insult that precipitated AKI include discontinuation of any offending agents (ie, nephrotoxins), hydration, maintenance of renal perfusion, and renal replacement therapy (RRT).

In this chapter, the definition, classification, epidemiology, and common etiologies of AKI are presented. Methods to recognize and assess the extent of kidney function loss are also discussed. Unique considerations for medication dosing adjustments and finally, preventive strategies for patients at risk and management approaches for those with established AKI are reviewed.

DEFINITION AND CLASSIFICATION OF ACUTE KIDNEY INJURY

① Several different definitions and classifications of AKI have been published, including the *R*isk, *I*njury, *F*ailure, *L*oss of Kidney Function, and *E*nd-Stage Kidney Disease (RIFLE), *A*cute *K*idney *I*njury *N*etwork (AKIN), and Kidney Disease: Improving Global Outcomes (KDIGO) classifications. Among these, the KDIGO criteria are the most commonly used for diagnosing and staging AKI (Table 61-1).[1–3] The KDIGO criteria have been validated across different patient populations and their staging correlates closely with hospital mortality, cost, and length of stay.[4–6]

TABLE 61-1

RIFLE, AKIN, and KDIGO Classification Schemes for AKI[a]

RIFLE Category	**S_{cr} and GFR[b] Criteria**	**Urine Output Criteria**
Risk	S_{cr} increase to 1.5-fold or GFR decrease >25% from baseline	<0.5 mL/kg/hr for ≥6 hours
Injury	S_{cr} increase to twofold or GFR decrease >50% from baseline	<0.5 mL/kg/hr for ≥12 hours
Failure	S_{cr} increase to threefold or GFR decrease >75% from baseline, or S_{cr} ≥4 mg/dL (354 µmol/L) with an acute increase of at least 0.5 mg/dL (44 µmol/L)	Anuria for ≥12 hours
Loss	Complete loss of function (RRT) for >4 weeks	
ESKD	RRT >3 months	
AKIN Criteria	**S_{cr} Criteria**	**Urine Output Criteria**
Stage 1	S_{cr} increase ≥0.3 mg/dL (27 µmol/L) or 1.5- to 2-fold from baseline	<0.5 mL/kg/hr for ≥6 hours
Stage 2	S_{cr} increase >2- to 3-fold from baseline	<0.5 mL/kg/hr for ≥12 hours
Stage 3	S_{cr} increase >3-fold from baseline, or S_{cr} ≥4 mg/dL (354 µmol/L) with an acute increase of at least 0.5 mg/dL (44 µmol/L), or need for RRT	<0.3 mL/kg/hr for ≥24 hours or anuria for ≥12 hours
KDIGO Criteria	**S_{cr} Criteria**	**Urine Output Criteria**
Stage 1	S_{cr} increase ≥0.3 mg/dL (27 µmol/L) or 1.5-1.9 times from baseline	<0.5 mL/kg/hr for 6-12 hours
Stage 2	S_{cr} increase 2-2.9 times from baseline	<0.5 mL/kg/hr for ≥12 hours
Stage 3	S_{cr} increase three times from baseline, or S_{cr} ≥4 mg/dL (354 µmol/L), or need for RRT, or eGFR[c] <35 mL/min/1.73 m^2 in patients <18 years	Anuria for ≥12 hours

[a] For all staging systems, the criterion that leads to worst possible diagnosis should be used.

[b] GFR calculated using the Modification of Diet in Renal Disease (MDRD) equation.

[c] GFR calculated using the Schwartz formula.

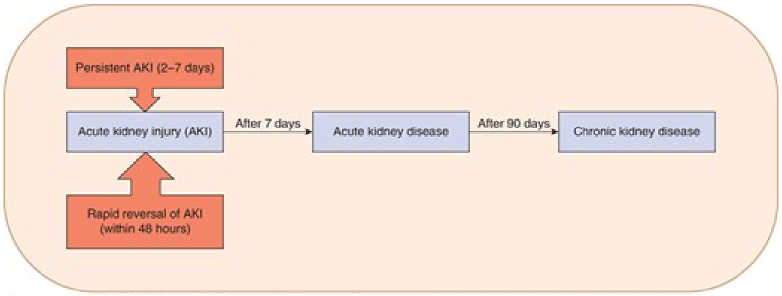
AKI, acute kidney injury; AKIN, Acute Kidney Injury Network; ESKD, end-stage kidney disease; eGFR, estimated glomerular filtration rate; h, hours; KDIGO, Kidney Disease: Improving Global Outcomes; RIFLE, Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease; RRT, renal replacement therapy; S_{cr}, serum creatinine.

Since the KDIGO staging system depends on S_{cr} and urine output as the main diagnostic criteria, it is associated with some inherent weaknesses. An increase in S_{cr} is usually evident roughly 1 or 2 days after development of AKI. This lag time in S_{cr} rise may delay diagnosis of AKI and adversely affect patient outcomes. Urine output decreases earlier and often is the first indicator of AKI but it is a fairly nonspecific marker. Documentation can be challenging, especially with patients able to independently void without ability to document urine output. In fact, patients with AKI can be nonoliguric (urine output greater than 500 mL/day), oliguric (urine output less than 500 mL/day), or anuric (urine output less than 50 mL/day). Urine output will also vary with volume status, diuretic administration or omission, and the presence of an obstruction.[7]

AKI becomes acute kidney disease (AKD) if kidney function is impaired beyond 7 days, and can ultimately transition into CKD if the duration exceeds 90 days (Fig. 61-1).[8] As such, there has been a growing recognition of the need to standardize AKI recovery. The Acute Disease Quality Initiative (ADQI) proposed to further subclassify AKI into those who recover within 48 hours of injury (rapid reversal of AKI) and those whose injury persists beyond 48 hours (persistent AKI).[8]

FIGURE 61-1

Continuum of impaired kidney function. Acute kidney injury is an abrupt decrease in kidney function that can either rapidly reverse within the first 48 hours or persist over a period of up to 7 days. Kidney impairment that persists beyond 7 days is termed acute kidney disease and can lead to chronic kidney disease if its duration exceeds 90 days.



Persistent AKI (2–7 days)
Acute kidney injury (AKI)
After 7 days
Acute kidney disease
After 90 days
Chronic kidney disease
Rapid reversal of AKI (within 48 hours)

EPIDEMIOLOGY

The epidemiology of AKI varies widely depending on the patient population studied and the criteria used to evaluate the patient. A recent CDC analysis from the National Inpatient Sample and the National Health Interview Surveys noted that the total number of AKI-related hospitalizations increased fourfold over the last two decades (from 953,926 in 2000 to 3,959,560 in 2014). Age-standardized rates of AKI hospitalizations increased 139% (23-55 per 1,000 persons) among diabetic adults and rose by 230% (3.5-11.7 per 1,000 persons) among non-diabetic adults.[9]

AKI occurs in 3.0% to 18.3% of hospitalized non-critically ill patients and 30% to 60% of critically ill adults.[10] Risk factors associated with AKI include the presence of CKD, diabetes, heart or liver disease, albuminuria, major surgery (especially cardiac surgery), acute decompensated heart failure, sepsis, hypotension, volume depletion (diarrhea, vomiting, or dehydration), medications (exposure to angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], aminoglycosides, etc.), advanced age, male gender, and African American race.[3,10–12]

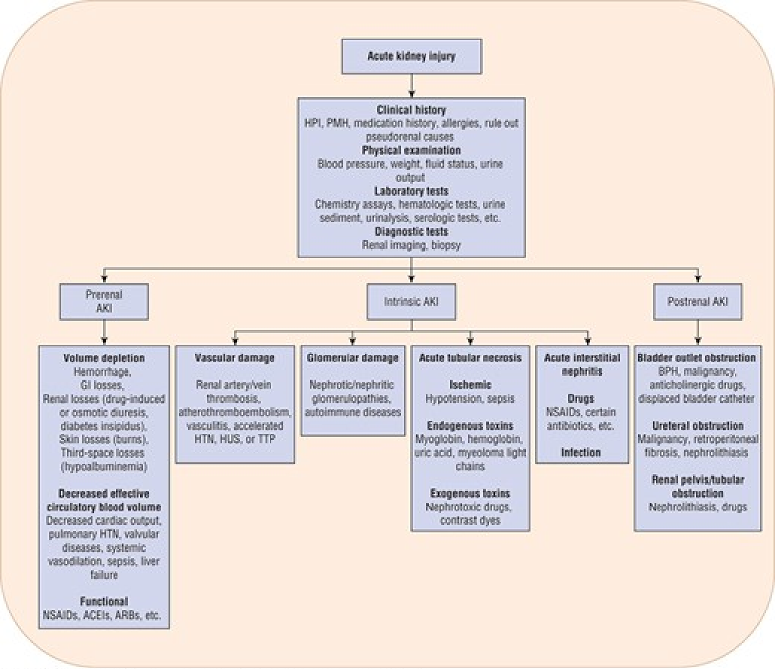
② Severity, duration, and frequency of AKI are important predictors of poor patient outcomes. Any degree of AKI is associated with an increased risk of death, and the odds increase with the severity of the insult.[10,12] For survivors of AKI, the development of some degree of CKD and need for RRT are other important considerations. In addition, AKI is associated with increased length of hospital stay, mortality, cost, readmission, ventilator days, and need for post-hospitalization care.[10,12,13]

ETIOLOGY

③ The etiology of AKI can be divided into three broad categories based on the anatomic location of the injury associated with the precipitating factor(s). The management of patients presenting with this disorder is largely predicated on identification of the specific etiology responsible for the patient's AKI (Fig. 61-2). Traditionally, the causes of AKI have been categorized as (a) prerenal, which results from decreased renal perfusion in the setting of undamaged parenchymal tissue, (b) intrinsic, the result of structural damage to the kidney, most commonly the tubule from an ischemic or toxic insult, and (c) postrenal, caused by obstruction of urine flow downstream from the kidney.

FIGURE 61-2

Classification of acute kidney injury (AKI) based on etiology. (ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BPH, benign prostatic hyperplasia; HPI, history of present illness; HTN, hypertension; HUS, hemolytic uremic syndrome; NSAIDs, nonsteroidal anti-inflammatory drugs; PMH, past medical history; TTP, thrombotic thrombocytopenic purpura)



Acute kidney injury
Clinical history
HPI, PMH, medication history, allergies, rule out pseudorenal causes
Physical examination
Blood pressure, weight, fluid status, urine output
Laboratory tests
Chemistry assays, hematologic tests, urine sediment, urinalysis, serologic tests, etc.
Diagnostic tests
Renal imaging, biopsy
Prerenal AKI
Intrinsic AKI
Postrenal AKI
Volume depletion
Hemorrhage, GI losses, Renal losses (drug-induced or osmotic diuresis, diabetes insipidus), Skin losses (burns), Third-space losses (hypoalbuminemia)
Decreased effective circulatory blood volume
Decreased cardiac output, pulmonary HTN, valvular diseases, systemic vasodilation, sepsis, liver failure
Functional
NSAIDs, ACEIs, ARBs, etc.
Vascular damage
Renal artery/vein thrombosis, atherothromboembolism, vasculitis, accelerated HTN, HUS, or TTP
Glomerular damage
Nephrotic/nephritic glomerulopathies, autoimmune diseases
Acute tubular necrosis
Ischemic
Hypotension, sepsis
Endogenous toxins
Myoglobin, hemoglobin, uric acid, myeloma light chains
Exogenous toxins
Nephrotoxic drugs, contrast dyes
Acute interstitial nephritis
Drugs
NSAIDs, certain antibiotics, etc.
Infection
Bladder outlet obstruction
BPH, malignancy, anticholinergic drugs, displaced bladder catheter
Ureteral obstruction
Malignancy, retroperitoneal fibrosis, nephrolithiasis
Renal pelvis/tubular obstruction
Nephrolithiasis, drugs

The risk of AKI increases substantially with decreasing glomerular filtration rate (GFR) and presence of albuminuria and underlying CKD. A history of AKI has also been associated with high risk for developing additional episodes of AKI and subsequent complications such as CKD.[10,14]

PATHOPHYSIOLOGY

The pathophysiologic processes involved in the development of the three traditional categories of AKI: prerenal AKI, intrinsic AKI, and postrenal AKI are described below.

Prerenal Acute Kidney Injury

Prerenal AKI or prerenal azotemia results from hypoperfusion of the renal parenchyma, with or without systemic arterial hypotension. Renal hypoperfusion associated with systemic arterial hypotension may be caused by a decline in either the intravascular volume or the effective circulating blood volume. Intravascular volume depletion may result from several conditions, including hemorrhage, excessive gastrointestinal (GI) losses (severe vomiting or diarrhea), dehydration, extensive burns, and diuretic therapy. Effective circulating blood volume may be reduced in conditions associated with a decreased cardiac output or blood flow to the kidney and systemic vasodilation. Renal hypoperfusion without systemic hypotension is most commonly associated with bilateral renal artery occlusion or unilateral occlusion in a patient with a single functioning kidney.

Patients with a mild reduction in effective circulating blood volume or volume depletion are generally able to maintain a normal GFR by activating several compensatory mechanisms. Those initial physiologic responses by the body stimulate the sympathetic nervous and the renin–angiotensin–aldosterone system and release antidiuretic hormone if hypotension is present. These responses work together to directly maintain blood pressure via vasoconstriction and stimulation of thirst, which in conscious patients results in increased fluid intake, as well as sodium and water retention. Additionally, GFR may be maintained by afferent arteriole dilation (mediated by intrarenal production of vasodilatory prostaglandins, kallikrein, kinins, and nitric oxide) and efferent arteriole constriction (mainly mediated by angiotensin II). In concert, these homeostatic mechanisms are often able to maintain arterial pressure and renal perfusion, potentially averting the progression to AKI.[15] If, however, the decreased renal perfusion is severe or prolonged, these compensatory mechanisms may be overwhelmed, and prerenal AKI will be clinically evident.

Patients at risk for prerenal AKI are particularly susceptible to changes in the afferent and efferent arteriolar tone, as they may not be able to compensate as readily. Some medications interfere with these renal adaptive responses, and the resulting reduction in the glomerular hydrostatic pressure precipitates an abrupt decline in GFR and is sometimes referred to as *functional AKI*. A common cause of this syndrome is a decrease in efferent arteriolar resistance as the result of initiation of an ACE inhibitor or ARB (see Chapter 65). For example, individuals with heart failure are often given an ACE inhibitor or ARB to help improve left ventricular function, but if the dose is titrated too rapidly, they may experience a decline in GFR. If the increase in the S_{cr} is less than 30% from baseline and potassium serum levels are within normal range, the medication can generally be continued. Nonsteroidal anti-inflammatory drugs (NSAIDs) may also precipitate AKI in susceptible individuals due to their impact on renal prostaglandin production and afferent arteriolar vasodilation, which some patients rely on to maintain GFR.[16]

Sepsis is one of the leading clinical conditions associated with AKI. The exact mechanism by which sepsis causes AKI is poorly understood. A complex interplay of different mechanisms may be involved in its pathogenesis, including disturbances in renal microcirculation, inflammation, and metabolic reprogramming.[17,18]

Intrinsic Acute Kidney Injury

Intrinsic AKI results from direct damage to the kidney and is categorized on the basis of the injured structures within the kidney: vasculature, glomeruli, tubules, and interstitium.

Renal Vasculature Damage

Occlusion of the larger renal vessels resulting in AKI is not common but can occur if large atheroemboli or thromboemboli occlude the bilateral renal arteries or one vessel of the patient with a single kidney. Atheroemboli most commonly develop during vascular procedures that cause atheroma dislodgement, such as angioplasty and aortic manipulations. Thromboemboli may arise from dislodgement of a mural thrombus in the left ventricle of a patient with severe heart failure or from the atria of a patient with atrial fibrillation. Renal artery thrombosis may occur in a similar fashion to coronary thrombosis, in which a thrombus forms in conjunction with an atherosclerotic plaque.

Although smaller vessels can also be obstructed by atheroemboli or thromboemboli, the damage is limited and the development of clinically significant AKI is unlikely. However, these small vessels are susceptible to inflammatory processes that lead to microvascular damage and vessel dysfunction when the renal capillaries are affected. Neutrophils invade the vessel wall, causing damage that can include thrombus formation, tissue infarction, and collagen deposition within the vessel structure. Diffuse renal vasculitis can be severe and promote concomitant ischemic acute tubular necrosis (ATN). Untreated hypertension may also compromise renal microvascular blood flow, causing diffuse renal capillary damage.

Glomerular Damage

Glomerular damage is an uncommon cause of AKI. The glomerulus serves to filter fluid and solute into the tubules while retaining proteins and other large blood components in the intravascular space. Kidney injury may develop when circulating immune complexes deposit in the glomeruli and cause an inflammatory reaction (eg, lupus nephritis, IgA nephropathy).[19] Details on the pathophysiology and specific therapeutic approaches to glomerulonephritis are described in Chapter e66.

Tubular Damage

Most intrinsic AKI cases are due to ATN, which can either result from renal ischemia or nephrotoxin exposure (eg, aminoglycosides, contrast dyes). The tubules located within the medulla of the kidney are particularly at risk for ischemic injury, as this portion of the kidney is metabolically active and thus has high oxygen requirements, yet, as compared with the cortex, receives relatively low oxygen delivery. Thus, ischemic conditions caused by severe hypotension or exposure to vasoconstrictive medications preferentially affect the tubules more than any other portion of the kidney.

The clinical evolution of ATN is characterized by four distinct phases: initiation, extension, maintenance, and recovery. Renal tubular epithelial cell injury is the hallmark of the initiation phase that results from vasoconstriction and ischemia, and leads to GFR reduction. Contrary to its name, ATN is not only characterized by necrosis and cell death but by a large spectrum of cellular injury that usually involves sublethal damage to the cells. The extent of injury depends not only on the severity and duration of ischemia but also on the sensitivity of renal cells to the insult which may vary based on the cells' metabolic demands, physical location within the kidney, degree of regional blood perfusion, oxygenation status, and membrane permeability. Further, alterations in cytoskeletal structure lead to a loss of epithelial polarity and barrier function. As a result, the glomerular filtrate starts leaking back into the interstitium and is reabsorbed into the systemic circulation. Additionally, urine flow is obstructed by accumulation of sloughed epithelial cells, cellular debris, and formation of casts.[19,20]

The extension phase is characterized by continued hypoxia following the initial ischemic event and an inflammatory response. Both events are more pronounced in the outer medullary region and the GFR continues to decrease. During the maintenance phase, GFR reaches a nadir during which cellular repair processes are initiated in an attempt to reestablish and maintain cellular and tubular integrity. The surviving cells undergo repair, migration, dedifferentiation, and proliferation. The maintenance phase is eventually followed by a recovery phase, during which new tubule cells are regenerated through redifferentiation and epithelial polarity is reestablished.[19,20]

Interstitial Damage

Acute interstitial nephritis (AIN) is an idiosyncratic delayed hypersensitivity immune reaction that is most commonly caused by medications (see Chapter 65) and less commonly by infections, autoimmune diseases, or idiopathic causes. AIN is characterized by tubular and interstitial inflammation, and edema with lesions composed of mononuclear cells, with a predominance of lymphocytes (primarily CD4+ T lymphocytes) and monocytes or macrophages. The specific pathogenic process depends on the cause of AIN. Medication-induced disease is characterized by renal interstitial dendritic and renal tubular epithelial cells recognition of the offending agent as immunogenic and their activation of T lymphocytes which induce proinflammatory molecules. Once acute interstitial inflammation sets in, it can progress rapidly to a more destructive fibrogenic process marked by increased interstitial matrix, ischemia, tubular atrophy, and interstitial fibrosis.[21,22] The prognosis of AIN varies depending on the specific cause, baseline kidney function, and timely detection of the offending agent; however, it is estimated that almost a quarter of patients may not recover their baseline kidney function.[22]

Postrenal Acute Kidney Injury

Postrenal AKI accounts for less than 5% of all cases of AKI and may develop as the result of obstruction at any level within the urinary collection system (see Fig. 61-2). However, if the obstructing process is above the bladder, it must involve both kidneys (one kidney in a patient with a single functioning kidney) to cause clinically significant AKI, as one functioning kidney can generally maintain a near-normal GFR. Bladder outlet obstruction, the most common cause of obstructive nephropathy, is often the result of a prostatic process in males (hypertrophy, cancer, or infection), producing a physical impingement on the urethra and thereby preventing the passage of urine. It may also be the result of an improperly placed urinary catheter. Blockage may also occur at the ureter level secondary to nephrolithiasis, blood clots, sloughed renal papillae, or physical compression by an abdominal process. Crystal deposition within the tubules from oxalate and some medications severe enough to cause AKI is uncommon, but it is possible in patients with severe volume contraction and in those receiving large doses of a medication with relatively low urine solubility (see Chapter 65).[19] Typically, these patients have insufficient urine volume to prevent crystal precipitation in the urine. Extremely elevated uric acid concentrations from chemotherapy-induced tumor lysis syndrome can cause obstruction and direct tubular injury as well.[23] Where ever the location of the obstruction, urine will accumulate in the renal structures above the obstruction and cause increased pressure upstream. The ureters, renal pelvis, and calyces all expand, and the net result is a decline in GFR. If renal vasoconstriction ensues, a further decrement in GFR will be observed.

CLINICAL PRESENTATION

The initiating signs or symptoms of AKI are highly variable and largely dependent on the underlying etiology. It may be a change in urinary character (eg, decreased urine output or urine discoloration), edema, electrolyte disturbances, sudden weight gain, or severe abdominal or flank pain. Early recognition and cause identification are critical, as they directly affect the outcome of AKI. One of the first steps in the diagnostic process is to determine if the change in kidney function is acute, chronic, or the result of an acute change in a patient with known CKD (also called acute-on-chronic kidney failure). Patients should also be promptly evaluated for any changes in their fluid and electrolyte status. Patients presenting with AKI in the outpatient environment may have nonspecific or seemingly unrelated symptoms so that the time of onset of the injury can be difficult to determine. On the other hand, AKI in hospitalized patients is often detected much earlier in its course due to frequent laboratory studies and daily (or hourly) patient assessments.

Patient Assessment

The assessment of a patient with AKI starts with a thorough review of his or her medical records, with a particular focus on chronic conditions, laboratory studies, procedures, and surgeries. An exhaustive review of prescription and nonprescription medicines, herbal products, and drugs of abuse may help determine if AKI was potentially precipitated by drug ingestion.

During the initial patient evaluation, presumptive signs and symptoms of AKI need to be differentiated from a potential new diagnosis of CKD. A medical history for kidney disease–related chronic conditions (eg, poorly controlled hypertension or diabetes mellitus), previous laboratory data documenting the presence of proteinuria or an elevated S_{cr}, and the finding of bilateral small kidneys on renal ultrasonography suggest the presence of new onset CKD rather than AKI. However, it is important to note that patients with CKD may develop episodes of AKI as well. In these patients, an abrupt rise in the baseline S_{cr} is one of the most useful indicators of the presence of an acute insult to the kidneys. The staging of AKI should also be assessed including the initial insult and decline in kidney function, stabilization of the decline in function, and recovery period.

An acute change in urinary habitus is another common and noticeable symptom associated with AKI. The presence of cola-colored urine is indicative of blood in the urine, a finding commonly associated with acute glomerulonephritis. In hospitalized patients, changes in urine output may be helpful in characterizing the cause of the patient's AKI. Acute anuria is typically caused by either complete urinary obstruction or a catastrophic event (eg, shock or acute cortical necrosis). Oliguria, which often develops over several days, suggests prerenal azotemia, whereas nonoliguric kidney failure usually results from acute intrinsic kidney failure or incomplete urinary obstruction.

Depending on the underlying cause of AKI, patients may present with a variety of symptoms affecting virtually any organ system of the body. Constitutional symptoms such as nausea, vomiting, fatigue, malaise, and weight gain are common but nonspecific. The onset of flank pain is suggestive of a urinary stone; however, if bilateral, it may suggest swelling of the kidneys secondary to acute glomerulonephritis or AIN. Complaints of severe headaches may suggest the presence of severe hypertension and vascular damage. The presence of fever, rash, and arthralgia may be indicative of medication-induced AIN or lupus nephritis.

A thorough physical examination is an important step in evaluating individuals with AKI, as clues regarding the etiology can be evident from the patient's head (eye examination) to toe (evidence of dependent edema) assessment. Evaluation of the patient's volume and hemodynamic status is critical as well, as it will guide management. For example, patients with prerenal AKI can present with either volume depletion or fluid overload. Volume depletion may be evidenced by the presence of postural hypotension, decreased jugular venous pressure (JVP), and dry mucous membranes. Fluid overload, on the other hand, is often reflected by elevated JVP, pitting edema, ascites, and pulmonary crackles.

Conventional Markers of Kidney Function

④ Common laboratory tests used to evaluate the patient with impaired kidney function are described in Chapter e60. Over the past four decades, S_{cr} has been the most widely used laboratory test for estimating creatinine clearance (CL_{cr}) and eGFR. However, there are several limitations associated with its use since it is affected by age, gender, muscle mass or evidence of acute breakdown, diet, hydration status and stability of the values (eg, S_{cr}) utilized. For example, patients with reduced creatinine production, such as those with low muscle mass, may have low values (less than 0.6 mg/dL [53 μmol/L]); thus, the presence of a gradual rise to normal values (0.8-1.2 mg/dL [71-106 μmol/L]) may actually suggest the presence of AKI. However, in the presence of improved nutrition and a large muscle mass, a S_{cr} of 1.2 mg/dL (106 μmol/L) may be a true representation of a person's current renal status. Instead of using only the most current value to determine kidney function, changes in the value from a patient's baseline over the past few days need to be considered. S_{cr} is normally inversely proportional to GFR. However, rapid changes in GFR disrupt this equilibrium and make S_{cr} an insensitive marker. In fact, changes in S_{cr} will lag behind the GFR's decline by 1 to 2 days due to slow accumulation, increased tubular secretion, and increased extrarenal clearance.[24,25] This can lead to an overestimation of the patient's GFR in the early stages of AKI and consequently a potential delay in the diagnosis of the syndrome.

⑤ Because S_{cr} steady-state values are assumed when one uses several GFR calculation methods, such as the Cockcroft-Gault and Chronic Kidney

Disease Epidemiology Collaboration (CKD-EPI) equations, they should not be used to estimate GFR in AKI patients with unstable kidney function. These equations will typically overestimate GFR when the AKI is worsening and underestimate it when the AKI is resolving. Instead, it may be useful to evaluate changes in S_{cr} values from the patient's baseline and also consider the S_{cr} sequence values to determine if kidney function is potentially improving or worsening. The most recent S_{cr} reflects the time-averaged kidney function over the preceding time period. Several mathematical approaches to estimate GFR in patients with unstable S_{cr} that incorporate the principles of creatinine accumulation and elimination have been proposed and are discussed in detail in Chapter e60. However, these methods have not been extensively validated in the setting of AKI, and their value for adjusting medication dosing is questionable. Additionally, these equations are complex and are not commonly used in the clinical setting.

Two other widely available markers of kidney function are BUN and urine output. The value of the BUN in AKI is limited because urea production and renal clearance are heavily influenced by extrarenal factors such as critical illness, volume status, protein intake, and medications. Urine output measured over a specified period of time (eg, 4-24 hours) allows for short-term assessment of kidney function, but its utility is limited to cases in which it is significantly decreased. The presence of anuria suggests complete kidney failure, whereas oliguria indicates some degree of kidney damage. Urine output needs to be interpreted with caution, as it is dependent on several factors, such as hydration status and medications. As mentioned earlier in the chapter, a patient may have AKI and still maintain a normal urine output; this condition is referred to as *nonoliguric AKI*. Another approach to estimating kidney function is to directly measure CL_{cr} over a short period of time, for example, 4 to 12 hours.[26] Although, potentially precise and simple to do, its accuracy is questionable if the urine output is low or the urine collection is incomplete.

In addition to BUN and S_{cr}, selected blood and urine tests, and urinary sediment are routinely evaluated to differentiate the cause of AKI and guide patient management. For example, a complete blood cell count with differential can help rule out infectious causes of AKI. Serum electrolyte values may be abnormal because of the acute decline of the kidney's ability to regulate electrolyte excretion. Particular attention should be paid to serum potassium, calcium, magnesium, and phosphorus values, which can be markedly elevated and cause life-threatening complications.

Given the limited usefulness of solely using S_{cr} or BUN concentrations to differentiate the etiology of AKI, urinary electrolytes and osmolality should be determined, and both a microscopic and chemical analysis of the urine should be performed (Table 61-2). The finding of a high urinary specific gravity, in the absence of glucosuria or mannitol administration, suggests an intact urinary concentrating mechanism and that the cause of the patient's AKI is likely prerenal azotemia. The presence of urinary protein is often difficult to interpret, especially in the setting of acute or chronic kidney failure. A patient with CKD may have a baseline proteinuria, thus clouding the clinical presentation, unless this is known at the time of AKI assessment. Classically, proteinuria is a hallmark of glomerular damage. However, tubular damage can also result in proteinuria, as the tubules are responsible for reabsorbing small proteins that are normally filtered by all glomeruli. The presence of blood also results in a positive urine protein test, so this confounder must always be assessed when a positive urine protein is obtained. Hematuria suggests acute intrinsic AKI secondary to glomerular injury, catheter related trauma, infection, or a kidney stone. On microscopic examination, the key findings are cells, casts, and crystals, and the presence of one or more of these may suggest specific etiologies of the AKI (Table 61-3). The finding of urinary crystals may indicate nephrolithiasis and a postrenal obstruction. If red blood cells or red blood cell casts are present, one should consider the presence of a physical injury to the glomerulus, renal parenchyma, or vascular beds. The finding of white blood cells or white blood cell casts suggests interstitial inflammation (ie, interstitial nephritis), which can be secondary to an allergic, granulomatous, or infectious process.

TABLE 61-2

Diagnostic Parameters for Differentiating Causes of AKI[a]

Laboratory Test	Prerenal AKI	Intrinsic AKI	Postrenal AKI
Urine sediment	Hyaline casts, may be normal	Granular casts, cellular debris	Cellular debris
Urinary RBC	None	2-4+	Variable
Urinary WBC	None	2-4+	1+
Urine Na (mEq/L or mmol/L)	<20	>40	>40
FE_{Na} (%)	<1	>2	Variable
Urine specific gravity	>1.018	<1.012	Variable

[a] Common laboratory tests are used to classify the cause of AKI. Functional AKI, which is not included in this table, would have laboratory values similar to those seen in prerenal AKI. The laboratory results listed under intrinsic AKI are those seen in acute tubular necrosis, the most common cause of intrinsic AKI.

AKI, acute kidney injury; FE_{Na}, fractional excretion of sodium; S_{cr}, serum creatinine; RBC, red blood cell; WBC, white blood cell.

TABLE 61-3

Urinary Findings as a Guide to the Etiology of AKI

Type of Urinary Evaluation	Presence of	Suggestive of
Urinalysis	Leukocyte esterases	Pyelonephritis
	Nitrites	Pyelonephritis
	Protein	
	Mild (<0.5 g/day)	Tubular damage
	Moderate (0.5-3 g/day)	Glomerulonephritis, pyelonephritis, tubular damage
	Large (>3 g/day)	Glomerulonephritis, nephrotic syndrome
	Hemoglobin	Glomerulonephritis, pyelonephritis, renal infarction, renal tumors, kidney stones
	Myoglobin	Rhabdomyolysis-associated tubular necrosis
	Urobilinogen	Hemolysis-associated tubular necrosis
Urine sediment	Microorganisms	Pyelonephritis
Cells	Red blood cells	Glomerulonephritis, pyelonephritis, renal infarction, papillary necrosis, renal tumors, kidney stones
	White blood cells	Pyelonephritis, interstitial nephritis
	Eosinophils	Drug-induced interstitial nephritis, renal transplant rejection
	Epithelial cells	Tubular necrosis
Casts	Granular casts	Tubular necrosis
	Hyaline casts	Prerenal azotemia
	White blood cell casts	Pyelonephritis, interstitial nephritis
	Red blood cell casts	Glomerulonephritis, renal infarct, lupus nephritis, vasculitis
Crystals	Urate	Postrenal obstruction
	Calcium phosphate	Postrenal obstruction

AKI, acute kidney injury.

Simultaneous measurement of urine and serum electrolytes is also helpful in the setting of AKI (see Table 61-3). From these values, a fractional excretion of sodium (FE_{Na}) can be calculated. The equation for the calculation of the FE_{Na} is as follows:

$$FE_{Na} = \frac{\text{Excreted}Na}{\text{Filtered}Na} \times 100 = \frac{U_{vol} \times U_{Na}}{GFR \times S_{Na}} \times 100$$
FENa=ExcretedNaFilteredNa×100=Uvol×UNaGFR×SNa×100

where

$$GFR = \frac{U_{vol} \times U_{cr}}{S_{cr} \times t}$$
GFR=Uvol×UcrScr×t

Thus:

$$FE_{Na} = \frac{U_{Na} \times S_{cr} \times 100}{U_{cr} \times S_N}$$
FENa=UNa×Scr×100Ucr×SN

where U_{vol} is the urine volume, U_{cr} is the urine creatinine concentration, U_{Na} is the urine sodium concentration, S_{cr} is the serum creatinine concentration, S_{Na} is the serum sodium concentration, which usually does not vary much, GFR is the glomerular filtration rate, and *t* is the time period over which the urine is collected.

The FE_{Na} is one of the better diagnostic parameters to differentiate the cause of AKI. A low urinary sodium concentration (less than 20 mEq/L [mmol/L]) and low FE_{Na} (less than 1%) in a patient with oliguria suggest that there is stimulation of the sodium-retentive mechanisms in the kidney and that tubular function is intact. These findings are most characteristic of prerenal azotemia. Unfortunately, diuretic use in the preceding days limits the usefulness of the FE_{Na} calculation by increasing natriuresis, even in hypovolemic patients. The fractional excretion of urea (FE_{Urea}), which can be calculated like FE_{Na}, is sometimes used as an alternative means to assess tubular function in patients receiving diuretics. The inability to concentrate urine results in a high FE_{Na} (greater than 2%), suggesting tubular damage as the primary cause of the intrinsic AKI. However, this is also not an absolute finding, as there are some intrinsic causes that can be associated with a low FE_{Na} (eg, contrast nephropathy, myoglobinuria, and interstitial nephritis). Highly concentrated urine (greater than 500 mOsm/kg [mmol/kg]) suggests stimulation of antidiuretic hormone and intact tubular function. These findings are consistent with prerenal azotemia.

Novel Biomarkers of Kidney Damage

A variety of biomarkers have been investigated to detect and predict the clinical outcomes of AKI. While they vary in their origin, function, distribution, and time of release following kidney injury, the large majority are molecules that are released as a result of direct kidney cell damage. The performance of most biomarkers is variable and depends on the patient population, cause of AKI, presence of comorbidities, and timing of biomarker measurements. In general, their ability to detect AKI is better within homogenous patient populations where the time of AKI is known than in heterogeneous populations with multiple comorbidities and unknown AKI time or cause such as critically ill patients. Even though some biomarker tests are now commercially available, these tests are not routinely available at most clinical practice sites.[27,28]

Two of the most promising biomarkers for use in AKI are tissue inhibitor of metalloproteinases 2 (TIMP-2) and insulin-like growth factor binding protein 7 (IGFBP7). Both molecules inhibit specific proteins that result in G1 cell cycle arrest noted to occur during the early phases of cellular stress or injury.[29] The combination of TIMP-2 and IGFBP7 was approved by the Food and Drug Administration (FDA) as the first point-of-care device (Nephrocheck®) to detect early AKI. The Nephrocheck® test uses a fluorescent immunoassay and reveals test results expressed as an AKI risk score within 20 minutes. A score over 0.3 $(\text{ng/mL})^2/1{,}000$ indicates high risk for developing moderate to severe AKI within 12 hours of testing. The cutoff value of 0.3 has a sensitivity of 95% and a specificity of only 46%. TIMP-2 and IGFBP7 have greatest predictability in patients at high risk for AKI, particularly patients who are critically ill, septic, or undergoing major surgery.[30] Nephrocheck® is not to be used as a standalone test for the diagnosis of AKI and should be used in conjunction with other diagnostic and clinical findings. Further, Nephrocheck® should be avoided in patients experiencing severe albuminuria and hyperbilirubinuria, as they interfere with the test results.[31]

Other biomarkers of kidney damage include neutrophil gelatinase–associated lipocalin (NGAL), kidney injury molecule 1 (KIM-1), interleukin 18 (IL-18), liver-type fatty acid binding protein (L-FABP), and N-acetyl-beta-D-glucosaminidase (NAG). They have been used for risk assessment, early detection, classification, and prognosis of AKI.[28,32] Since novel AKI biomarkers are still not widely utilized in clinical practice, the ADQI published a consensus statement on how AKI biomarkers can be integrated into a patient-centered approach to improve AKI care.[33] The panel recommends using AKI biomarkers to identify patients at risk who would benefit from preventative treatment. Further, they suggest using biomarkers to guide AKI management and predict AKI recovery and duration. It is important to note that these biomarkers would be used in addition to and not as a replacement for clinical assessment and standardized tests for kidney function such as S_{cr} and urine output.[32,33]

The advances in our knowledge of AKI pathophysiology as well as the advent of biomarkers has prompted ADQI to propose the use of two new terms "functional change" and "kidney damage." Functional change refers to changes in glomerular and tubular function and includes markers such as S_{cr}, eGFR, and cystatin C. Kidney damage describes the presence of tubular and/or glomerular injury and includes markers such as TIMP-2 and IGFBP7. The rationale behind the proposed changes in terminology stems from the recognition of subclinical kidney injury. According to this, kidney injury may be detected by changes in the plasma or urinary levels of specific biomarkers before overt changes in kidney function (decreased eGFR or increased S_{cr}) have occurred. As a result, a patient may have kidney damage without a change in kidney function. Since this patient group is at a greater risk of complications, a longer stay in intensive care unit, and has a higher risk of dying when compared with the group without kidney damage, they may benefit from preventative interventions geared towards minimizing progression and toxicity (ie, avoidance or cessation of nephrotoxic drugs). The ADQI group has proposed the use of functional and damage markers, along with clinical information, to improve diagnostic accuracy, etiology, and staging of AKI.[33] Table 61-4 summarizes the relationship between functional change and kidney damage.[34,35]

TABLE 61-4

Classification of AKI Based on Functional and Kidney Damage Biomarkers

		Kidney Damage	
	No	**Yes**	
Loss of function	**No**	No loss of function or damage; Biomarker negative KDIGO negative	Kidney damage without loss of function Biomarker positive KDIGO negative
	Yes	Loss of function but no kidney damage KDIGO positive Biomarker negative	Loss of function and presence of kidney damage KDIGO positive Biomarker positive

AKI, acute kidney injury; KDIGO, Kidney Disease Improving Renal Outcomes.

Diagnostic Considerations

When the source of kidney injury is unclear after reviewing the patient's history, physical examination, and assessment of laboratory values, imaging techniques such as abdominal radiography, including the kidneys, ureters, and bladder (KUB), computed tomography (CT), and ultrasonography may be helpful. These may reveal small, shrunken kidneys indicative of CKD. Postrenal obstruction can often be identified with a renal ultrasonography and/or CT scan. Renal ultrasonography is also useful in detecting obstruction or hydronephrosis. Nephrolithiasis as small as 5 nm or a narrowing of the ureteral tract can be detected by ultrasonography or more sensitive tests, such as KUB and CT. When the cause of AKI is not evident, renal biopsies are useful in determining the cause in most patients. Because of the associated risk of bleeding, a renal biopsy is rarely undertaken and should only be performed in those circumstances when a definitive diagnosis is needed to guide therapy, such as the precise etiology of glomerulonephritis (see Chapter e66).

PREVENTION OF ACUTE KIDNEY INJURY

Prevention of AKI is critical since there is no treatment to reverse the insult once it has developed. Several nonpharmacologic and pharmacologic options to reduce the risk of AKI are described below.

Desired Outcomes

The goals of AKI prevention are to (a) screen and identify patients at risk, (b) monitor high-risk patients until the risk has subsided, and (c) implement prevention strategies when appropriate.

General Approach to Prevention

⑥ The choice of preventive strategy depends on the patient's risk factors for AKI such as comorbidities, planned procedures, and medications, to name a few.

Sometimes, the risk of kidney injury is predictable, such as in the setting of decreased perfusion secondary to compromised cardiac function (eg, post coronary bypass surgery) or secondary to the administration of a nephrotoxic agent like radiocontrast dye. In these situations, the potential insult to the kidneys cannot be avoided but may be preventable or minimized with intravenous fluids and/or avoidance or removal of any additional insults. In the inpatient setting, volume status optimization, hemodynamic support, and careful assessment of the risk versus benefit of potentially nephrotoxic medications are commonly recommended strategies for the prevention of AKI.

Nonpharmacologic and Pharmacologic Strategies for Prevention of AKI

Electronic Alert Systems

Advances in electronic health record (EHR) systems have led to the development of clinical decision support systems and electronic alerts designed to improve and standardize care in certain high-risk patient populations. Electronic alerts have been used for early detection of AKI and increased surveillance of patients on nephrotoxic medications. In general, alerts lead to greater implementation of the intervention, lower loss of kidney function, and decreased exposure to nephrotoxins.[36–38] For example, use of an EHR generated screening tool to identify pediatric patients receiving nephrotoxic medications and to recommend daily S_{cr} monitoring, switching a nephrotoxic drug to a non-nephrotoxic alternative or therapeutic drug monitoring, as appropriate has resulted in a 23% decrease in AKI rates and 42% decrease in AKI intensity.[39] Electronic alerts have the potential to reduce AKI by focusing on more appropriate medication prescribing and monitoring.

In addition to EHR systems, advances in machine learning technology have led to development of AKI risk prediction models. So far, there is an increasing amount of evidence that these machine learning models are effective in predicting AKI, typically within the following 24 to 72 hours.[40–42] While the application of machine learning in nephrology is still relatively new and not widely available in clinical practice, it has potential to improve patient outcomes in the future.

Intravenous Fluids

Intravenous fluids are one of the primary interventions that have consistently shown benefit and are routinely used in the prevention of AKI, particularly in patients with hemodynamic instability secondary to intravascular volume depletion as well as in patients receiving radiocontrast agents before a radiologic procedure.

Hemodynamic instability and systemic hypotension increase the risk of AKI as they can lead to decreased renal perfusion and subsequent kidney injury. Both isotonic crystalloids and colloid-containing solutions have been used for intravascular volume replacement. Among colloids, synthetic products such as hyperoncotic hydroxyethyl starch (HES) have been associated with impaired kidney function and should generally be avoided.[43] Albumin does not increase the risk of AKI and specific patient populations such as those with cirrhosis and spontaneous bacterial peritonitis may benefit from its therapy.[44] It has been hypothesized that albumin may offer additional advantages to septic patients as it is the main protein responsible for maintaining plasma colloid osmotic pressure, it has antioxidant and anti-inflammatory properties, and acts as a scavenger for reactive oxygen and nitrogen species. However, major patient outcomes such as risk of AKI, need for RRT, and mortality, are comparable between albumin replacement therapy and isotonic saline.[45] Now, the 2012 KDIGO guidelines recommend isotonic crystalloids over colloids for intravascular volume expansion in patients at risk for AKI.[3]

When using crystalloid solutions, options include either balanced solutions or isotonic saline. Use of balanced fluids over normal saline in acutely ill individuals likely decreases risk of AKI, need for RRT, and death.[46–48] The main concerns associated with the use of large amounts of saline are hyperchloremic acidosis since the chloride content in isotonic saline is 1.5 times that of plasma (154 mEq/L [mmol/L]). Hyperchloremia in turn can decrease renal artery blood flow and renal tissue perfusion. Further, saline infusions cause a greater increase in interstitial fluid volume than balanced solutions, which may result in increased renal volume and intracapsular pressure, decreased microvascular blood flow, and impaired kidney function.[49] On the other hand, balanced solutions such as Ringer's lactate, Hartmann's solution, and PlasmaLyte have an electrolyte composition similar to human plasma, and do not increase risk of hyperchloremic acidosis.

In addition to correcting hemodynamic instability and hypovolemia, fluids are the mainstay of therapy for the prevention of contrast-induced acute kidney injury (CI-AKI). CI-AKI is a common cause of ATN in the inpatient setting (see Chapter 65 for a detailed discussion of CI-AKI).[50]

While administration of intravenous fluids clearly has a critical role in AKI prevention, fluids need to be used judiciously as volume overload can have deleterious effects on the kidneys. The majority of crystalloid solutions redistribute into the interstitial space and can lead to interstitial edema, increased intraabdominal pressure, decreased renal oxygen delivery, and decreased GFR. In fact, poorer outcomes may be observed in patients with fluid overload including increased risk of AKI and decreased recovery of kidney function.[51] Hence, fluid administration beyond reestablishing euvolemia is generally not recommended.

Glycemic Control

In critical illness, both hyper- and hypoglycemia are associated with adverse patient outcomes.[52] Hyperglycemia can occur secondary to stress, inflammation, or medications (eg, steroids) while hypoglycemia can develop secondary to decreased clearance of insulin, interruptions in nutrition support prior to procedures, or tight insulin protocols. Tight glycemic control with target glucose levels of 80 to 110 mg/dL (4.4-6.1 mmol/L) may significantly decrease the risk of AKI and this has been adopted in the ICU setting.[53,54] However, tight glycemic control protocols may also increase risk of hypoglycemia and mortality.[52,55,56] As a result, a more moderate approach to glycemic control is favored in the critically ill. Guidelines from the American Diabetes Association and Surviving Sepsis Campaign recommend a glycemic target range of 140 to 180 mg/dL (7.8-10 mmol/L) and less than 180 mg/dL (10 mmol/L), respectively, in critically ill patients.[57,58]

TREATMENT OF ACUTE KIDNEY INJURY

⑦ Since there is no specific treatment that can reverse AKI or hasten its recovery, supportive measures that focus on hemodynamics, fluid balance, acid-base balance, and electrolyte homeostasis are the mainstays of therapy.

Desired Outcomes

Short-term goals of AKI management include minimizing the degree of insult to the kidney, reducing extrarenal complications, and expediting the patient's recovery of kidney function. Therapy should focus on maintaining organ functions while sustaining mean arterial pressure goals. The ultimate goal is to have the patient's kidney function restored to pre-AKI baseline.

General Approach to Treatment

Identification and management of AKI should be prompt. At times, the most effective method for managing AKI may be treatment of the precipitating event. A review of a patient's medications should be conducted to determine if a nephrotoxic agent could be the potential cause of AKI. Additionally, if possible, exposure to nephrotoxic agents should be limited either by discontinuation or switching to a less nephrotoxic option. Prerenal AKI should be managed with hemodynamic support and volume replacement, intrinsic AKI management relies on managing the cause and providing supportive care, and postrenal AKI therapy should focus on removing the cause of the obstruction. At the same time, patient's comorbidities need to be reviewed, as disease states such as cardiac and liver failure may require introduce additional management challenges.

Pharmacologic and Nonpharmacologic Strategies for Treatment of AKI

There is no cure for AKI. Thus, management of AKI focuses on supportive care and managing resultant complications, which includes hemodynamic instability, fluid overload, electrolyte imbalances, and acid-base abnormalities. In initial stages of AKI or mild disease, pharmacologic therapy may be sufficient, but patients with more severe AKI, RRT may be necessary to maintain fluid, electrolyte, and acid-base balance while removing accumulating waste products or toxins.

Fluid Management

Maintaining an adequate fluid status is imperative but also challenging, working to balance the need for volume resuscitation and fluid overload. First-line therapies for volume resuscitation consist of intravenous fluids, while fluid overload may need to be treated with loop diuretics or RRT.[3] Additionally, administration of all intravenous fluids should also be evaluated to determine if any notable reduction in daily intake can be achieved. This can be accomplished by concentrating intravenous medications to deliver less fluid overall or switching intravenous medication to the enteral route.

Intravenous Fluids

The principal of fluid therapy is to maintain or restore effective intravascular volume to assure adequate renal perfusion. In selected settings such as sepsis, low oncotic pressures and leaky vasculature can pose a challenge by leading to excessive extracellular fluid and anasarca with intravenous fluid administration. Similar to preventative hydration strategies, intravenous fluids need to be used judiciously as both volume depletion and fluid overload can adversely affect kidney function and increase morbidity and mortality.

Intravenous fluids should be administered to patients who have a prerenal AKI caused by hypovolemia or patients experiencing hemodynamic instability resulting from hypovolemia. The goal of fluid administration should be to restore and maintain euvolemia. In order to reduce the risk for fluid overload, slower correction strategies with either small intravenous boluses or short-term infusions of crystalloid fluids should be administered. Frequent reassessment of volume and hemodynamic status should be completed to determine further need for or changes to fluid therapy. As previously noted, balanced crystalloid solutions may be preferred for patients requiring IV fluids (eg, resuscitation) since isotonic saline has been associated with hyperchloremic metabolic acidosis and death in critically ill adults.[47,59,60] The patient should be monitored for fluid intake (both enteral and intravenous), urine output, insensible losses (ie, vomiting, diarrhea, excessive perspiration) which may not captured in overall documented daily totals of fluid loss, pulmonary and peripheral edema, blood pressure (target mean arterial pressure ≥65 mm Hg), and serum electrolytes. Urine output ≥0.5 mL/kg/hr is generally targeted during the initial fluid resuscitation phase.[57] Assessing documentation of fluid balance in the EHR should consider that a patient's independent drinking or urinary voiding or excessive perspiration may not be captured. When this occurs, changes in a patient's weight can assist in validating fluid status.

If AKI is a result of blood loss or is complicated by symptomatic anemia, red blood cell transfusion to a hemoglobin > 7 g/dL (70 g/L; 4.34 mmol/L) is the treatment of choice.[57] Once a hemoglobin of > 7 g/dL (70 g/L; 4.34 mmol/L) is reached, balanced solutions or normal saline can be used to restore intravascular volume. In patients with cardiac failure, fluids should only be administered if intravascular volume is depleted. Albumin is typically preferred in individuals with severe hypoalbuminemia secondary to cirrhosis or nephrotic syndrome.[44] In critically ill patients with vasodilatory shock, vasopressors such as norepinephrine and vasopressin may be used in conjunction with fluids in order to maintain adequate hemodynamics and renal perfusion.[3]

Diuretics

Loop diuretics are frequently prescribed for the management of fluid overload in patients with established kidney injury and often as a precursor to RRT. Loop diuretics have several theoretical advantages: increased urine output, decreased risk of ischemic injury by inhibiting the Na-K-Cl cotransporter and thus decreasing oxygen demand, and enhanced renal blood flow due to increased availability of renal prostaglandins. Enhancing urine output from oliguric to nonoliguric may be beneficial in itself, as nonoliguric AKI is associated with better outcomes than oliguric AKI.[61] However, even though loop diuretics increase urine output, they may not improve patient outcomes (ie, mortality, need for RRT) for patients with established AKI.[61,62] Therefore, the KDIGO guidelines recommend limiting the use of loop diuretics to the management of fluid overload and avoiding their use for the purpose of treatment of AKI.[3]

Diuretic resistance is a relatively common problem in patients with AKI for several reasons. Excessive sodium administration (eg, normal saline) may override the ability of the diuretics to eliminate sodium. Also, patients with ATN have a reduced number of functioning nephrons on which the diuretic may exert its action upon. In other clinical states such as glomerulonephritis, heavy proteinuria can occur. In these patients, intraluminal loop diuretics cannot exert their effect in the loop of Henle if they are extensively bound to proteins present in the urine. Still other patients may have greatly reduced bioavailability of oral furosemide because of intestinal edema, often associated with high preload states, which further reduces oral furosemide absorption. Lastly, the braking phenomenon, which is a progressively decreasing response to natriuresis associated with repeated administration of a loop diuretic, may also lead to diuretic resistance.[61,63] Table 61-5 includes possible therapeutic options to counteract each form of diuretic resistance.

TABLE 61-5

Common Causes of Diuretic Resistance in Patients with AKI

Causes of Diuretic Resistance	Potential Therapeutic Solutions
Excessive sodium intake (sources may be dietary, IV fluids, and drugs)	Remove sodium from nutritional sources and medications
Inadequate diuretic dose or inappropriate regimen	Increase dose, increase frequency, use continuous infusion or add thiazide
Reduced oral bioavailability (usually furosemide)	Use parenteral therapy, switch to oral torsemide or bumetanide
Nephrotic syndrome (loop diuretic protein binding in tubule lumen)	Increase dose, add thiazide
Reduced renal blood flow	
Drugs (NSAIDs, ACEIs, vasodilators)	Discontinue these drugs if possible
Intravascular depletion	Intravascular volume expansion
Increased sodium resorption	
Distal nephron hyperthrophy	Add thiazide, sodium restriction
Postdiuretic sodium retention	Dietary sodium restriction, use continuous infusion
Heart failure	Assess effective circulatory volume, increase dose, increase frequency, use continuous infusion
Cirrhosis	Assess effective circulatory volume, consider paracentesis
Acute tubular necrosis	Increase diuretic dose, diuretic combination therapy

ACEIs, angiotensin-converting enzyme inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs.

The most common therapeutic option to overcome diuretic resistance is to use higher doses of intravenous loop diuretics. Often, patients with impaired kidney function have lower rates of diuretic secretion into the tubular fluid; consequently, higher doses of loop diuretics are prescribed. Caution must be taken when increasing intermittent bolus doses as the risk of adverse reactions such as ototoxicity also increases due to higher corresponding peak concentrations achieved too quickly. To avoid rapid high peak concentrations when using furosemide, doses of less than 160 mg can be administered undiluted no faster than a rate of 20 to 40 mg/minute, whereas doses exceeding 160 mg can be diluted and administered via a short infusion at a rate no faster than 4 mg/min. Another option to avoid high peak concentrations and post-diuretic sodium retention is to administer loop diuretics as a continuous infusion. Administration via a continuous infusion can achieve the same degree of diuresis with lower doses and results in no difference in mortality or hospital length of stay. An initial loading dose is recommended prior to the initiation of a continuous infusion of furosemide or its equivalent to decrease the time to the medication's onset of action.[63] One disadvantage of using a continuous infusion is it requires more extensive and frequent monitoring, as infusion rates are usually based on an hourly urine output goal. Typically, increasing intermittent bolus doses or increasing dosing frequency are trialed before implementing the more labor-intensive continuous infusion strategy.

Another approach to overcome diuretic resistance in AKI is to use a loop diuretic in combination with a diuretic from a different pharmacologic class. Diuretics that work at the distal convoluted tubule (chlorothiazide and metolazone) or the collecting duct (amiloride, triamterene, and spironolactone) may have a synergistic effect when administered with loop diuretics by blocking the compensatory increase in sodium and chloride reabsorption (see Chapter 68, Disorders of Sodium and Water Homeostasis). Thiazide diuretics are most commonly used in combination with loop diuretics. Oral metolazone is used most often because, unlike other thiazides, it produces effective diuresis at a CL_{cr} less than 20 mL/min (0.33 mL/s). Oral metolazone is frequently given 30 minutes prior to intravenous loop diuretics to achieve peak effects at the same time to potentially enhance diuresis. The combination of thiazide and thiazide-type diuretics and a loop diuretic has been used successfully in the management of fluid overload. When such combinations are used, the regimen should be assessed for any improved or enhanced diuresis and determine if the regimen should be continued.[63]

While diuretic strategies are being used, symptoms of ototoxicity, fluid status, and serum creatinine and electrolytes (ie, potassium, sodium, magnesium, calcium, BUN) should be closely monitored, especially with aggressive strategies such as larger doses of diuretics and continuous infusions. The goal of diuretic therapy in the setting of fluid overload is to achieve adequate urine output to accomplish a net negative diuresis. Net negative diuresis, or achieving a fluid output that is higher than fluid intake, is desired. Strict intake and output measures are best accomplished when a patient has a urinary catheter to monitor urine volume or is located in the intensive care unit where any changes are frequently assessed and documented. In patients who do not have a urinary catheter, accurate assessment of urine output can be challenging and a patient's weight should be closely followed. Daily goals for diuretic therapy should be a net negative diuresis of 500 to 1,000 mL of urine per day or a weight loss of 0.5 to 1 kg per day as tolerated. Once a patient has reached euvolemic status, diuretics should either be discontinued or dose adjusted to maintain the patient's fluid balance.

Electrolyte and Acid-Base Management

The most common electrolyte disorder encountered in AKI patients is hyperkalemia, as >90% of potassium is renally eliminated. Life-threatening cardiac arrhythmias may occur with serum potassium concentrations greater than 6 mEq/L (mmol/L), so frequent monitoring of potassium is essential. Medications and foods with high amounts of potassium (antibiotics, oral phosphorous replacement powders, alkalinizers, potassium salt substitutes,) should be avoided (see Chapter 70, Disorders of Potassium and Magnesium Homeostasis). Some medications may promote potassium retention by the kidneys (spironolactone, eplerenone, finerenone) and should also be avoided or closely monitored if used (see Chapter 70). In general, exogenous potassium supplementation should be avoided in patients with AKI unless warranted by the presence of hypokalemia. Medications that can cause an increase of potassium such as ACE inhibitors, ARBs, and sulfamethoxazole-trimethoprim should be avoided.

Other electrolytes abnormalities include hyperphosphatemia and hypocalcemia. These electrolytes are eliminated by the kidneys and, unlike potassium, are not efficiently removed by dialysis. Hyperphosphatemia can be particularly high in patients with tissue destruction (eg, trauma, rhabdomyolysis, and tumor lysis syndrome) due to substantial amounts of phosphorus released from the destroyed tissue. Typically, the dietary intake of phosphorus needs to be restricted in advanced stages of AKI. When phosphorus is particularly high, phosphate binding agents (eg, calcium acetate, sevelamer hydrochloride) may be considered. Caution should be taken when using calcium-containing phosphate binding agents or calcium-containing antacids in situations where hypercalcemia is present to prevent precipitation of calcium phosphate which can lead to soft tissue calcification. In contrast to the patient with CKD, AKI patients do not usually develop calcium imbalance secondary to the limited duration of the illness. Hypocalcemia can develop as a result of hyperphosphatemia; thus, the treatment of hyperphosphatemia should correct the imbalance. Additionally, hypocalcemia can be seen in patients who are receiving continuous renal replacement therapy (CRRT) along with a concomitant infusion of regional citrate being used for anticoagulation. Typically, citrate is infused before the renal replacement machine's dialyzer/hemofilter to bind serum calcium in order to prevent the extracorporeal circuit from clotting which leaves less calcium to return to circulation. Since severe hypocalcemia can result in arrhythmias or even death, frequent monitoring of unbound serum calcium concentrations and supplementation with parenteral calcium is necessary to maintain normocalcemia.

Metabolic acidosis can also occur in patients with severe AKI due to the kidney's inability to adequately excrete acid. This can be a result of AKI itself or from other conditions that are common in critically ill patients, such as shock due to severe hypoperfusion. Determining and correcting the underlying cause of the acid-base imbalance is imperative. Supplementation with bicarbonate therapy can be utilized in patients with mild acidosis to temporarily correct the derangement. RRT may need to be initiated if the underlying cause cannot be reversed promptly or in patients with severe life-threatening acidosis.

Nutritional Considerations in AKI

Nutritional management of critically ill patients with AKI can be extremely complex, as it needs to account for metabolic derangements resulting from both impaired kidney function and underlying disease processes, as well as the effects of RRT on nutrient balance. Loss of the normal physiologic and metabolic functions of the kidney and the hypercatabolic response to stress and injury will have an impact on the metabolism of nutrients. Derangements in glucose, lipid, and protein metabolism result in hyperglycemia and insulin resistance, hypertriglyceridemia, protein catabolism, and negative nitrogen balance. The latter, in particular, is problematic to manage, as increased amino acid turnover and skeletal muscle breakdown lead to muscle wasting and malnutrition that does not respond well to increasing exogenous protein supplementation. The KDIGO guidelines recommend a caloric intake goal of 20 to 30 kcal/kg/day (84-126 kJ/kg/day) irrespective of the stage of kidney impairment and preferentially through the enteral route. In the setting of noncatabolic AKI without need for dialysis, 0.8 to 1 g/kg/day of protein is suggested and 1 to 1.5 g/kg/day if patient is receiving RRT.[3] CRRT is associated with an increased removal of small water-soluble molecules such as amino acids and certain nutrients. As a result, hypercatabolic patients receiving CRRT will typically have higher protein requirements up to a maximum of 1.7 g/kg/day.[3] The Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines for nutrition in patients with AKI recommend a caloric intake goal of 25 to 30 kcal/kg/day (105-126 kJ/kg/day). In the ICU setting, up to 2.5 g/kg/day of protein is suggested if patient is receiving RRT.[64]

Renal Replacement Therapy

⑧ Renal replacement therapy is often utilized to treat life threatening indications resulting from severe AKI. These indications include fluid overload, electrolyte disturbances (eg, hyperkalemia), acid-base imbalances, uremic complications, oliguria or anuria, and pulmonary edema from fluid overload. Multiple factors influence decisions to initiate dialysis including specific timing and type of modality.[3,65–69] The most common indications for initiation of RRT are summarized in Table 61-6. In the setting of AKI, the mode of delivery of RRT can be either intermittent hemodialysis or continuous RRT and the chosen modality usually depends on physician preference and the resources (ie, healthcare professionals, machines) available. No difference in mortality or dialysis dependence has been shown between patients who received continuous or intermittent forms of RRT; however, continuous RRT is generally preferred in hemodynamically unstable patients.[3,67,70]

TABLE 61-6

Common Indications for RRT

Indication for RRT	Clinical Setting
A: *a*cid-base abnormalities	Metabolic acidosis (especially if pH <7.2)
E: *e*lectrolyte imbalance	Severe hyperkalemia and/or hypermagnesemia
I: *i*ntoxications	Salicylates, lithium, methanol, ethylene glycol, theophylline, phenobarbital
O: fluid *o*verload	Fluid overload (especially pulmonary edema unresponsive to diuretics)
U: *u*remia	Uremia or associated complications (neuropathy, encephalopathy, pericarditis)

RRT, renal replacement therapy.

Intermittent Hemodialysis

Intermittent hemodialysis (IHD) is the most frequently used RRT (see Chapter 64). Hemodialysis treatments usually last 3 to 4 hours and thus can achieve the rapid removal of volume and solutes and thereby contribute to correction of most of the electrolyte abnormalities associated with AKI. The primary challenge with this modality is hypotension, which is typically caused by the rapid removal of intravascular volume over a short period of time. Achieving prompt venous access for dialysis can be difficult in hypotensive patients and can limit the effectiveness of IHD. This can result in a lack of solute clearance, an inability to correct metabolic derangements, continued volume overload, and can lead to delayed recovery because of further ischemic insults to the kidneys. Patients with dialysis-dependent CKD generally achieve adequate solute and volume control with three times weekly dialysis, but hypercatabolic, fluid-overloaded patients with AKI may require more frequent hemodialysis treatments. Chapter 64 provides a detailed explanation of the principles and processes of IHD.

Continuous Renal Replacement Therapy

CRRT is a viable option to manage hemodynamically unstable patients with AKI, especially those who cannot tolerate rapid volume removal. Unlike IHD treatments that last a few hours, CRRT runs continuously 24 hours a day, providing a slower and more consistent removal of solutes and fluid over time. In general, CRRT can achieve a greater amount of solute removal with higher mean arterial pressures compared with IHD in critically ill patients with AKI.[70] CRRT use is most commonly considered for those patients with higher acuity because of their intolerance of IHD-associated hypotension. The KDIGO guidelines suggest using CRRT over IHD in hemodynamically unstable patients.[3]

Several CRRT variants have been developed, including continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). These modalities differ in the degree of both their solute removal as well as fluid clearance and the modality chosen is based on an individual patient’s needs. The removal of solutes and fluid can be achieved via three different mechanisms: diffusion, convection, and membrane adsorption. In CVVH, solute and fluid clearance is primarily a result of convection, the active transport of drug molecules at the concentration at which they exist in plasma water into the ultrafiltrate using a pump-driven pressure gradient, known as “solvent drag,” then fluid absent of solutes is replaced (Fig. 61-3). CVVHD provides a more extensive solute removal that works primarily by diffusion, where solute molecules passively move down a concentration gradient from an area of higher concentration (plasma) pass through the dialysis membrane to an area of lower concentration (dialysate). CVVHDF combines both convection and hemodialysis, achieving even higher solute and fluid removal rates (Fig. 61-3).

FIGURE 61-3

Several renal replacement therapies are commonly used in patients with acute kidney injury (AKI), including one of the three primary continuous renal replacement therapy (CRRT) variants: (a) continuous venovenous hemofiltration (CVVH), (b) continuous venovenous hemodialysis (CVVHD), (c) continuous venovenous hemodiafiltration (CVVHDF), and the hybrid intermittent hemodialysis therapy, and (d) sustained low-efficiency daily dialysis (SLEDD). The blood circuit in each diagram is represented in red, the hemofilter/dialyzer membrane is yellow, and the ultrafiltration/dialysate compartment is brown. Excess body water and accumulated endogenous waste products are removed solely by convection when CVVH is employed. With CVVHD, waste products are predominantly removed as the result of passive diffusion from the blood, where they are in high concentration to the dialysate. The degree of fluid removal that is accomplished by convection is usually minimal. CVVHDF uses convection to a degree similar to that employed during CVVH as well as diffusion, and thus is often associated with the highest clearance of medications and waste products. Finally, SLEDD employs lower blood and dialysate flow rates than intermittent hemodialysis (IHD), but because of its extended duration, it is a gentler means of achieving adequate waste product and fluid removal.

Optimal timing of CRRT initiation has not been clearly established. Whether early initiation of RRT has improved morbidity and mortality benefit versus delaying RRT to allow for the possibility for a patient to recover function without needing RRT has been the subject of considerable debate. In situations when severe or life-threatening complications of AKI are present such as oliguria, pulmonary edema, or metabolic disorders (eg, acidosis, hyperkalemia, uremia), the indication for CRRT is clear. However, in the absence of such complications, the exact timing of CRRT initiation is uncertain. In fact, early initiation of CRRT at the onset of AKI may not demonstrate a mortality benefit or improve patient outcomes.[66,71,72] Clinicians are advised to carefully consider the patient’s overall clinical status, severity of kidney impairment and related complications, and trends in the patient’s physiologic and laboratory values before deciding whether and when to initiate CRRT.[68]

Anticoagulation is a major consideration for patients receiving CRRT as circuit clotting and filter patency can limit CRRT performance. It is important to note that the drivers for thrombosis and bleeding in severe kidney impairment are unique to this population, creating some limitations in applying approaches utilized in patients with more intact function. Typical anticoagulation is achieved by the administration of parenteral agents such as unfractionated heparin or regional citrate. Unfractionated heparin is widely available and easy to monitor but it also systemically anticoagulates the patient leading to an increased risk of bleeding. Regional citrate chelates ionized calcium in the extracorporeal circuit and impairs progression of the coagulation cascade. In order to maintain physiologic levels of calcium in the patient’s systemic circulation when using regional citrate, most protocols require infusion of parenteral calcium (ie, calcium chloride or calcium gluconate) prior to returning the blood to the patient as well as frequent monitoring of ionized calcium levels. When compared to unfractionated heparin, regional citrate is associated with less circuit clotting and longer filter lifetimes. Also, the risk of bleeding is lower as anticoagulation is limited to the extracorporeal circuit and does not extend to the patient. However, regional citrate increases the production of bicarbonate secondary to dissociation of the calcium-citrate complexes in the liver, which can increase the risk of metabolic alkalosis.[73] The goals of citrate anticoagulation are to maintain the circuit ionized calcium between 0.8 and 1.6 mg/dL (0.2-0.4 mmol/L), and the patient’s systemic ionized calcium between 4.4 and 5.2 mg/dL (1.1-1.3 mmol/L).[3] Now, the KDIGO Work Group recommends regional citrate as the preferred anticoagulant of choice for patients receiving CRRT.[3]

Other anticoagulants may be used in patients receiving CRRT but their use is less common or only recommended in select circumstances. Low-molecular weight heparins are generally not recommended due to increased cost, poor removal by CRRT, and limited supporting data. Argatroban or bivalirudin, which are direct thrombin inhibitors, is typically reserved for patients with contraindications to heparin such as antithrombin deficiency or heparin-induced thrombocytopenia.[3,73] Overall, the specific approach to anticoagulation depends on whether there is a need to limit anticoagulation to the circuit alone or extend it to systemically anticoagulate the patient. Many patients on CRRT require systemic anticoagulation for an underlying comorbidity (eg, atrial fibrillation and artificial heart valve) and will not need additional anticoagulation for RRT. As a result, the need for anticoagulation and the specific anticoagulant of choice should be tailored to individual patient requirements and corresponding indications.

Challenges with CRRT may include limited availability of the specialized equipment and other resources necessary to provide the treatments and to individualize the IV replacement, dialysate fluids, and medication therapy adjustments. Also, medication dosing requirements for patients who are receiving CRRT are complex and not clearly defined.[74] CRRT use is most commonly considered for those patients with higher acuity because of their intolerance of IHD-associated hypotension. The KDIGO guidelines suggest using CRRT over IHD in hemodynamically unstable patients.[3]

Prolonged Intermittent Renal Replacement Therapies

An alternative to CRRT is prolonged intermittent RRT (PIRRT), which has had a variety of names including extended-duration IHD, hybrid IHD, sustained low-efficiency dialysis (SLED), or sustained low efficiency daily dialysis (SLEDD) (see Fig. 61-3). These therapies use conventional dialysis machines but lower blood (150-200 mL/min) and dialysate (300-400 mL/min) flow rates with extended treatment periods of 6 to 12 hours. For critically ill patients with AKI, they are comparable to CRRT for hemodynamic control.[69] Although the use of PIRRT is increasing, our knowledge of its impact on medication removal is limited.[75] Differences in the prescribed parameters used in PIRRT, including frequency, duration, and dialysate flow rates, along with limited data on medication dosing in PIRRT present challenges to health care providers responsible for appropriate medication selection and dosing.[76–78]

Medication Dosing Considerations in AKI

⑨ Optimization of medication therapy for patients experiencing AKI is often challenging. The multiple variables influencing responses to the medication regimen include the patient’s residual drug clearance, fluid accumulation, comorbidities, and whether they need renal support with RRT. In addition, the patient’s current kidney function state and corresponding drug elimination influenced by the decline, stabilization or recovery of AKI should be considered. For renally eliminated medications, particularly for agents with a narrow therapeutic range, serum drug concentration measurements and assessment of pharmacodynamic responses are likely to be necessary. If hepatic function is normal, choosing an agent eliminated primarily by the liver may be preferred. However, renally eliminated active metabolites may accumulate to a point where they may elicit an undesired pharmacologic effect. Kidney failure can also independently impair nonrenal drug elimination including metabolism through “organ crosstalk,” where the dysfunction of one organ affects another.[79] Unfortunately, pharmacokinetic studies in patients with established AKI are limited.

The use of dosing guidelines based on data derived from patients with stable CKD may not reflect the clearance and volume of distribution in critically ill AKI patients. CKD dosing recommendations generally assume a stable rate of decline and do not take into account the dynamic changes seen in AKI (see Chapter 67).[74] In general, medication elimination may be more robust in AKI compared to CKD, suggesting some caution with utilizing CKD data for dosing decisions.[80] In some situations with sepsis and presence of AKI, immediate reductions in dosing for selected agents such as antibiotics should be cautioned as it may lead to under treatment. With the exception of vancomycin or aminoglycosides, full doses or extended infusions of antibiotics should be considered for the first 24 hours and re-evaluated.[81]

Pharmacotherapy regimen decisions should take into consideration the four distinct phases of AKI described earlier, specifically initiation, extension, maintenance, and recovery phase. The initiation and extension phases occur right after the kidney insult. First, a clinical determination should be made about the severity of AKI and degree of residual renal clearance. Then, in order to determine if medication therapy modifications are needed, the clinician should consider the goals of therapy, the specific pharmacokinetics of the medication, the potential for increased risk for an adverse drug event, and therapeutic drug monitoring (if available) (see Fig. 61-4). In AKI, the severity and timing of the decline in kidney function is relatively unpredictable, so frequent monitoring and reevaluation of medication dosing is necessary. Urine output is a good surrogate marker to monitor kidney function and prospectively assess where kidney function is trending. S_{cr} measurements lag behind kidney function; that is, today’s S_{cr} measurements typically reflect yesterday’s kidney function, and thus, S_{cr} is not a good marker for monitoring kidney function. In the next phase, maintenance, kidney function stabilizes and medication therapy regimens may require fewer alterations. The fourth and final phase is recovery, where AKI begins to resolve and there may be a need to increase the medication dose due to enhanced renal clearance. It is critically important to follow the patient closely and recognize trends for decreasing or improving kidney function in an effort to achieve and maintain medication therapy management goals.

FIGURE 61-4

Relationship between kidney function changes in AKI and dosing of renally eliminated drugs. As kidney function fluctuates in AKI, plasma drug concentrations will be affected. (A) If no dosing adjustments are made, then this will lead to supratherapeutic concentrations [depicted by green line] which can lead to adverse effects. In order to maintain target drug concentrations, dosing adjustments should be made as fluctuations occur. (B) When kidney function declines, a dosing regimen should be adjusted by decreasing the dose or frequency to maintain plasma drug concentrations in the therapeutic range [depicted by red line]. When kidney function improves, the dosing regimen should be changed by increasing the dose or frequency.

Edema, which is common in AKI, can increase the volume of distribution of many medications, particularly water-soluble compounds with relatively small volumes of distribution. Increased fluid distribution into the tissues (ie, sepsis and anasarca in heart failure) can also contribute to a larger volume of distribution for many medications and thereby reduce the proportion of medication in the plasma that is available to be removed by the kidneys. Because AKI frequently occurs in critically ill patients, multisystem organ failure is often an accompanying problem. In addition to volume overload, reductions in cardiac output or liver function can alter the pharmacokinetic profile of most medications. For selected renally eliminated medications or related metabolites with narrow therapeutic windows, close follow-up and dosing adjustments may be necessary.[74,75]

If rapid onset of activity is desired, a loading dose may be necessary to promptly achieve desired serum concentrations because the expanded volume of distribution and the prolonged elimination half-life extend the time (3.5 times the half-life) needed to reach steady-state concentrations. Maintenance dosing regimens should be reviewed frequently and be based on the assessment of the patient's most current kidney function. A dose that provides the desired serum concentration on 1 day may be inappropriate a few days later if there is a change in the patient's fluid status or kidney function has dramatically changed, or if RRT is initiated, changed, or discontinued (see Fig. 61-4).[74]

Medication therapy individualization in patients with AKI is complicated by the fact that patients with AKI may have a higher residual nonrenal clearance than patients with CKD who have a similar CL_{cr}.[74] Alterations in the activity of some, but not all, cytochrome P450 enzymes have been demonstrated in patients with CKD.[79,80] This may be the result of less accumulation of uremic waste products that may alter hepatic function. If a patient with AKI has higher than anticipated nonrenal clearance, this would result in more robust elimination leading to lower than expected, possibly subtherapeutic, serum concentrations. For example, to maintain comparable serum concentrations, the imipenem dose requirement in patients with AKI would be 2,000 mg divided daily as compared with the recommended dosage for patients with ESRD of 1,000 mg daily. As AKI persists, the nonrenal clearance values approach those observed in patients with CKD.[82] Another challenge associated with medication dosing in patients with AKI is that much of the dosing-related data were acquired in patients with CKD, with initial pharmacokinetic assessments done after single-dose administration. The determination of pharmacokinetic parameters using a single-dose model may result in overestimated initial medication removal secondary to simultaneous distribution from the plasma to the tissue.[83] In conclusion, the application of dosing regimens derived from patients with CKD and ESRD in addition to the use of more aggressive RRT approaches may result in underdosing of certain medications and thereby contribute to less than optimal clinical outcomes.

Medication Dosing Considerations in RRT

There are several physicochemical and pharmacokinetic characteristics that can alter medication clearance during RRT, including molecular weight, protein binding, volume of distribution, and degree of renal clearance or fraction eliminated by the kidneys.[83,84] Medication dosage regimen design considerations specific to patients receiving peritoneal dialysis and IHD are presented in Chapter 67. However, medication-dosing requirements for patients with AKI or CKD who are receiving CRRT are complex and not as clearly defined as in IHD.[74,81] Inadequately dosed medications in critically ill patients with AKI requiring RRT may be one factor contributing to the lack of improving outcomes with newer RRT approaches.

In general, RRT-mediated medication clearance is inversely related to molecular weight, such that RRT medication clearance decreases as the weight of a medication increases. IHD efficiently clears medications with a small molecular weight (ie, <500 Da), whereas CRRTs can efficiently clear much larger solutes (ie, <15,000 Da). High protein binding (>80%) can also affect clearance in both IHD and CRRT as the drug-protein complexes increase molecular weight significantly (eg, >50,000 Da), thus making it difficult for the complexes to pass through the pores in the hemofilter.[83,84] Conversely, patients who are experiencing hypoalbuminemia will have a higher fraction of unbound drug, thus a larger amount of the agent may be removed during RRT depending on the weight of the drug and its primary mode of elimination (eg, liver, kidney). Compounds with a large volume of distribution (V_D) of >1 L/kg are extensively distributed to extravascular tissues, leaving only a small fraction of the drug in the vascular compartment and thereby limiting drug removal.[74,81,83] Renal clearance of a drug also plays a role in determining RRT removal. In general, medications that are predominantly cleared by the kidney are more likely to be cleared via CRRT than medications that are eliminated primarily by nonrenal mechanisms.

There are marked differences in medication removal between the different CRRT modalities. Since CVVH relies on convection, medication removal is independent of molecular size of the medication or presence of a concentration gradient. Thus, it is the most efficient means of removing larger molecules (<15,000 Da) and those that are primarily not protein bound in the plasma. Another parameter that can assist in determining the likelihood of medication removal during use of convective RRT modalities is the sieving coefficient (SC), which is the ratio of a solute or medication in the ultrafiltrate to that in plasma. A SC of 1 indicates free transport across the membrane where a SC of 0 indicates no transport across the membrane. The SC is often approximated by the fraction unbound (f_u), or the fraction of drug unbound to protein in the plasma, because the ratios are often similar, and this information may be more readily available than SC. In CVVHD, medication removal relies on diffusion, which is an efficient means of removal of smaller molecules (<500 Da). Since CVVHDF is a combination of both convection and diffusion, medication removal is enhanced.

Limitations of using IHD-based dosing recommendations in patients receiving RRT for AKI include variability in the patient’s individual pharmacokinetic parameters, differences in the dialysis prescription, such as dialyzer blood flow or duration, unpredictability of dialysis timing based on availability, use of new hemodialyzers, and advances in the technology without knowing how medications are impacted. Pharmacokinetic and medication dosing assessments in patients with impaired kidney function often are performed after single dose administration to stable CKD subjects. Distribution and clearance estimates in this setting may not reflect those observed at steady and may be over-estimated.[84,85] The RRT approach used may also change on an hourly or daily basis, especially in hemodynamically unstable individuals. The approach can also be affected by a failure of the circuit, the need for a procedure, or the availability of a machine. Individualization of a dosing regimen may require daily assessment of the clinical status of the patient and any planned or administered hemodialysis. Renally eliminated drugs with narrow therapeutic ranges may benefit from additional orders to contact the patient’s healthcare providers if dialysis is stopped.[86]

Overall, there are numerous potential pharmacokinetic and pharmacodynamic alterations to be aware of in the patient with AKI. Individualization of pharmacotherapy for a patient receiving RRT is dependent on the patient’s residual kidney function, the clearance of the medication by CRRT, as well as the properties of the medication (ie, molecular weight, V_D, protein binding, and SC). In CRRT, the frequency of therapy interruptions will also impact medication removal and corresponding dosing requirements. Unfortunately, there is still a scarcity of data to quantify these changes, and even less evidence demonstrating that if one incorporates these considerations into patient care, the associated outcomes will be improved.

EVALUATION OF THERAPEUTIC OUTCOMES

Vigilant monitoring of patients with AKI is essential, particularly in those who are critically ill. Table 61-7 summarizes the main monitoring parameters for patients with established AKI.

TABLE 61-7

Key Monitoring Parameters for Patients with Established AKI[a]

Parameter	Frequency
Fluid ins & outs	Hourly/Every shift
Patient weight	Daily
Hemodynamics (blood pressure, heart rate, mean arterial pressure, etc.)	Hourly/Every shift
Blood chemistries	
Sodium, potassium, chloride, bicarbonate, calcium, phosphate, magnesium	Daily
Blood urea nitrogen/serum creatinine	Daily
Drugs and their dosing regimens	Daily
Nutritional regimen	Daily
Blood glucose	Daily (minimum)
Therapeutic drug monitoring of renally cleared drugs (eg, vancomycin aminoglycosides)	Highly variable, about three times weekly
Times of administered doses	Daily
Doses relative to administration of renal replacement therapy	Daily (unless unanticipated changes occur)
Urinalysis	
Calculate measured creatinine clearance	Every time measured urine collection performed
Calculate fractional excretion of sodium	Every time measured urine collection performed
Plans for renal replacement therapy	Daily

[a] Phlebotomy should be coordinated to minimize excessive blood draws.

Once the laboratory-based tests (eg, urinalysis and FE_{Na} calculations) have been conducted to diagnose the cause of AKI, they usually do not have to be repeated. In established AKI, daily measurements of fluid intake and output are usually adequate. Urine output should be measured more frequently in critically ill, hemodynamic instability, or more severe AKI. Monitoring diuretic response is also important. Vital signs should be monitored at least daily, and more often if the acuity of illness warrants. Electrolytes, BUN, and S_{cr} should be considered routine and measured at least daily for hospitalized patients. Electrolytes may need to be monitored more frequently in patients who are receiving enhanced diuretic strategies or on RRT. For medications influenced by RRT, the need for dose adjustments should be assessed daily or anytime RRT is interrupted, discontinued, or a change in modality or rate has been made.

The presence of renally eliminated medications should be assessed frequently. Therapeutic drug monitoring should be performed for medications that have a narrow therapeutic index if results can be obtained in a timely fashion. For patients receiving IHD, measuring a pre-dialysis serum drug concentration has the advantage of allowing time for the result to be reported and the next dose calculated so that it can be administered soon after dialysis. This is especially important if the desired pharmacologic effects are lost during or after hemodialysis because the serum concentration has become subtherapeutic. Serum concentrations drawn right after hemodialysis may reflect plasma concentrations that are transiently depressed until the medication can reequilibrate from the tissues (ie, a redistribution or rebound effect). The advantage of collecting a post-dialysis sample is the greater accuracy in determining how much medication was removed during hemodialysis. The down side of this strategy is that it delays dosing calculations and the administration of the next dose and ultimately delays the reestablishment of the target concentrations.

CONCLUSION

The unique characteristics of AKI can lead to notable differences in how kidney function is measured and how treatment regimens are developed. Most management approaches involve both prevention and supportive strategies, so as to minimize the potential for additional harm to the kidney. Understanding the constantly changing status inherent to AKI and how to adjust medication regimens is a key component to optimizing therapy.

SELF-ASSESSMENT QUESTIONS

1. A 71-year-old male, long-term care resident is admitted to the hospital with altered mental status. His admission laboratory values show a blood urea nitrogen (BUN) of 43 mg/dL (15.4 mmol/L), serum creatinine (Scr) of 2.8 mg/dL (248 µmol/L). Urinalysis reveals presence of white blood cells, red blood cells, and granular casts. His calculated fractional excretion of sodium (FeNa) is 2.2%. Whch of the following is the most likely etiology of his acute kidney injury?

   A. Intrinsic acute kidney injury

   B. Bladder obstruction

C. Postrenal acute kidney injury

D. Functional acute kidney injury

2. A 56-year-old male presents to the hospital with acute kidney injury. Based on the Kidney Disease Improving Renal Outcomes (KDIGO) classification system, which of the following parameters should be used to determine the stage of his kidney injury?

A. Serum creatinine

B. Estimated glomerular filtration rate

C. Serum creatinine or blood urea nitrogen

D. Serum creatinine or urine output

3. A 52-year-old (80 kg) man is in the intensive care unit with sepsis and acute kidney injury. Over the last 24 hours, his serum creatinine increased from a baseline of 0.9 mg/dL to 1.9 mg/dL (80-168 μmol/L) and he has had 100 mL/hr of urine output for the last 6 hours. His urinalysis is positive for the presence of epithelial cells, granular casts, and WBCs. According to the Kidney Disease Improving Global Outcomes (KDIGO) AKI classification, which stage of acute kidney injury does this patient have?

A. Stage I

B. Stage II

C. Stage III

D. Stage IV

4. A 53-year-old male is receiving furosemide IV for the treatment of fluid overload. If his response to furosemide decreases, all of the following strategies can be utilized to overcome diuretic resistance EXCEPT ___

A. Increase dose of furosemide

B. Change furosemide to a continuous infusion

C. Change furosemide from intravenous to oral route

D. Add oral metolazone

5. A 36-year-old male is diagnosed with intrinsic acute kidney injury secondary to a prolonged exposure to intravenous tobramycin. Which of the following pathophysiologic processes has most likely occurred in this case?

A. Glomerular damage secondary to severe inflammation

B. Drug hypersensitivity reaction leading to interstitial inflammation

C. Bladder outlet obstruction

D. Tubular epithelial cell damage

6. A 82-year-old female is admitted to the medical intensive care unit with acute kidney injury (AKI). Her labs indicate the following: Na 133 mEq/L (mmol/L), K 4.8 mEq/L (mmol/L), Cl 95 mEq/L (mmol/L), CO_2 22 mEq/L (mmol/L), PO_4 6.6 mg/dL (2.13 mmol/L), Ca 8.1 mg/dL (2.03 mmol/L), BUN 33 mg/dL (11.8 mmol/L), and S_{cr} 2.8 mg/dL (248 μmol/L). Which of the following electrolyte abnormalities does she have that are commonly found in patients with AKI?

A. Hyperphosphatemia

B. Hyperkalemia

C. Hyponatremia

D. Hypercalcemia

7. Which of the following medications is most likely to cause of prerenal acute kidney injury in a 75-year-old hospitalized patient?

   A. Tobramycin

   B. Acyclovir

   C. Contrast dyes

   D. Lisinopril

8. Per 2012 KDIGO AKI guidelines, which of the following intravenous fluids is recommended as first-line therapy for the prevention of acute kidney injury?

   A. 0.45% Saline

   B. PlasmaLyte

   C. 20% Albumin

   D. 0.25% Saline

9. Which of the following dialysis modalities is/are most likely to cause hypotension?

   A. Intermittent hemodialysis

   B. CVVH

   C. CVVHD

   D. Sustained low-efficiency dialysis (SLED)

10. A 72-year-old critically ill male with acute kidney injury requires vancomycin, a renally cleared antibiotic, for the treatment of ventilator-associated pneumonia. When determining how to individualize vancomycin dosing for this patient, all of the following parameters need to be taken into account EXCEPT:

    A. Serum phosphorus levels

    B. Serum creatinine

    C. Urine output

    D. Utilization of renal replacement therapy

11. Which of the following statements about drug dosing considerations in renal replacement therapy is CORRECT?

    A. Drug clearances attained by intermittent hemodialysis, continuous renal replacement therapy (CRRT), and hybrid renal replacement therapy are generally similar.

    B. Drug clearance is dependent on a drug's physiochemical properties.

    C. Drug clearance is similar across all CRRT modalities.

   D. Principles of drug clearance are more clearly defined for CRRT than IHD.

12. Electronic health record alerts may prevent acute kidney injury by helping healthcare providers ___

   A. Distinguish between patients with acute kidney injury and those with chronic kidney disease

   B. Identify patients at risk for acute kidney injury

   C. Renally dose medications

   D. Identify patients requiring renal replacement therapy

13. One major advantage of novel biomarkers such as tissue inhibitor of metalloproteinases 2 (TIMP-2) and insulin-like growth factor binding protein 7 (IGFBP7) is that they can ____

   A. Detect early acute kidney injury (AKI)

   B. Detect which patients will develop chronic kidney disease

   C. Stage patient's severity of AKI

   D. Predict recovery from chronic kidney disease

14. Which of the following is considered an indication for RRT?

   A. Metabolic acidosis

   B. Hypernatremia

   C. Pneumonia

   D. Cardiac failure

15. Which of the following anticoagulants used in CRRT is associated with hypocalcemia?

   A. Unfractionated heparin

   B. Fondaparinux

   C. Bivalrudin

   D. Regional citrate

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Patient urinalysis and laboratory findings (particularly presence of granular casts and a FeNa >2%) indicate the presence of intrinsic acute kidney injury. Patients with prerenal functional AKI will typically have a FeNa <1% and no cells in their urinalysis. Patients with obstruction or postrenal AKI will need further diagnostic testing such as imaging to confirm presence of an obstruction. See the "Clinical Presentation" section and Table 61-3 for further details.

2. **D.** KDIGO Classification utilizes changes in serum creatinine and/or urine output to stage patients with acute kidney injury. For all staging systems, the criterion (eg, Scr, UOP, GFR) that leads to worst possible diagnosis should be used. See the "Definition and Classification" section for more information.

3. **B.** Patient's UOP is 1.25 mL/kg/hr for the last 6 hours, which doesn't fit any Stage Classification. However, his baseline serum creatinine increased 2 to 2.9 fold, which places him into Stage II. The criterion (eg, Scr, UOP, GFR) that leads to worst possible diagnosis should be used. See Table 61-1 for

more information related to classification of patients with acute kidney injury.

4. **C.** All the listed interventions would be appropriate to overcome diuretic resistance except changing furosemide to oral route. Fluid overloaded patients may have intestinal edema which can reduce oral bioavailability of furosemide. As a result, intravenous route is preferred in most hospitalized patients. See the "Treatment" section and Table 61-7 for more information.

5. **D.** Intrinsic kidney injury is typically associated with tubular epithelial damage and is commonly observed with the administration of aminoglycosides such as tobramycin. See the "Pathophysiology" section for more information.

6. **A.** Patients with AKI will typically present with hyperphosphatemia and hyperkalemia as both phosphorus and potassium are mainly excreted by the kidneys. They can also develop hypocalcemia as a result of hyperphosphatemia or due to the use of regional citrate anticoagulation. Since the patient's serum potassium levels are within normal range, hyperphosphatemia is the most likely electrolyte abnormality associated with her AKI diagnosis. See the "Clinical Presentation" section for more information

7. **D.** ACE-inhibitors such as lisinopril are typically associated with prerenal acute kidney injury while other listed medications are not. See the "Pathophysiology" section for more information.

8. **B.** Isotonic fluids such as 0.9% saline or balanced solutions (ie, Plasmalyte) are preferred fluids for the prevention of acute kidney injury. Hypotonic fluids largely distribute intracellularly. Lastly, 20% albumin is typically reserved for hypoalbuminemic patients with cirrhosis or nephrotic syndrome. See the "Prevention" section for further information.

9. **A.** Intermittent hemodialysis is most likely to cause hypotension due to shorter duration and higher blood flow rates. See the "Renal Replacement Therapy" section for more information.

10. **A.** All of the listed parameters affect vancomycin clearance and need to be taken into account with the exception of serum phosphorus levels. Even though hyperphosphatemia is common in patients with AKI, it does not seem to interfere with vancomycin dosing recommendations. See the "Renal Replacement Therapy" section for more information.

11. **B.** Drug clearance is dependent on physiochemical properties such as protein binding and molecular weight. However, IHD and CRRT are all renal replacement modalities that vary in terms of efficiency of solute and water removal. Additionally, efficiency varies within each CRRT modality. See the "Drug Dosing Considerations in Renal Replacement Therapy" section for more information.

12. **B.** Electronic health record alerts may be useful in identifying patients at risk for acute kidney injury, for example, patients receiving multiple nephrotoxic medications. See the "Prevention" section for more information.

13. **A.** Novel biomarkers can detect early AKI. A score over 0.3 $(\text{ng/mL})^2/1{,}000$ indicates high risk for developing moderate-to-severe AKI within 12 hours of testing. See the "Clinical Presentation" section for more information.

14. **A.** Life threatening complications of AKI are indications for RRT which includes fluid overload, electrolyte disturbances (eg, hyperkalemia), acid-base imbalances, uremic complications, oliguria or anuria, and pulmonary edema from fluid overload Metabolic acidosis. See the "Renal Replacement" section for more information.

15. **D.** Regional citrate is a preferred method of circuit anticoagulation in CRRT as it does not systemically anticoagulate the patient and it is associated with less circuit clotting. However, it works by chelating ionized calcium in the extracorporeal circuit, leading to less calcium that is returned to circulation. See the "Continuous Renal Replacement Therapy" section for more information.

Chapter 62: Chronic Kidney Disease

Lori D. Wazny

KEY CONCEPTS

KEY CONCEPTS

① Chronic kidney disease (CKD) is classified based on the cause of kidney disease, assessment of glomerular filtration rate, and extent of albuminuria over at least a 3-month period.

② Guidelines from the Kidney Disease: Improving Global Outcomes (KDIGO) provide information to assist healthcare providers in clinical decision making and the design of appropriate therapy to manage CKD progression and the associated complications.

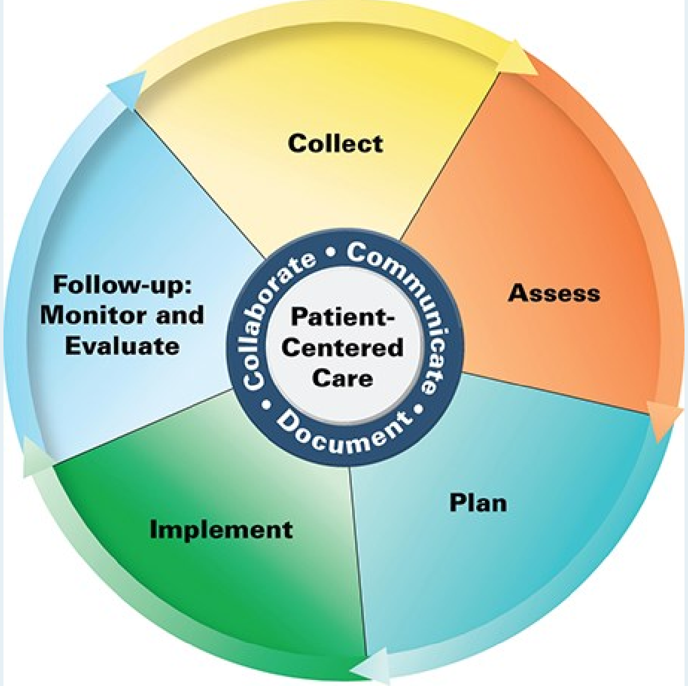
③ Patient education and shared decision making play a critical role in the appropriate management of patients with CKD. Studies of multidisciplinary teams in CKD clinics have demonstrated significant benefits in slowing progression of CKD and reduced mortality.

④ Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) are primary pharmacologic treatments to delay progression of CKD in patients with category A2-A3 albuminuria because of their effects on renal hemodynamics to reduce intraglomerular pressure and albuminuria.

⑤ Sodium Glucose Transport-2 inhibitors (SGLT2i) have emerged as the latest treatment to prevent progression to later stages of CKD and ESRD in patients with Type 2 diabetes and other kidney diseases associated with albuminuria.

PATIENT CARE PROCESS

Patient Care Process for Chronic Kidney Disease (CKD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, CKD stage [see Fig. 62-1] and cause of CKD, medication allergies)
- Past medical history
- Social history (eg, smoking), family/friend supports
- Current medications including OTC (eg, NSAID use), herbals, dietary supplements
- Objective data:
  - ◦ Blood pressure, heart rate, weight
  - ◦ Labs as outlined in Table 62-4

Assess

- Serum creatinine, glomerular filtration rate (GFR), or creatinine clearance
- Presence of albuminuria (see Fig. 62-1)
- Serum potassium concentration - assess frequently in patients with CKD and heart failure requiring adjustment of diuretics and/or ACEI
- Blood pressure (see targets in Fig. 62-3) - consider use of home blood pressure monitor
- Insurance coverage of medications, current out of pocket cost of medications
- Medication adherence
- Potential drug interactions

- Need for renal dose adjustments
- Other recommendations as outlined in Table 62-2 (eg, vaccines, lifestyle modifications)

Plan

- Drug therapy recommendations, including dose, route, frequency, and duration
- Monitoring parameters, including frequency and timing of follow-up
- Patient education, including purpose of new or changed treatment, medication side effects, medication administration
- Self-monitoring for resolution of symptoms and blood pressure targets, medication to hold on sick days if vomiting or diarrhea occur (eg, ACEI/ARB; SGLT2 inhibitors)
- Referrals to other providers when appropriate (eg, dietitian, occupational therapist, social worker, endocrinologist, CKD clinic)

Implement*

- Provide patient education on all elements of the treatment plan
- Use motivational interviewing strategies to maximize adherence
- Schedule follow-up labs, adherence assessment

Follow-up: Monitor and Evaluate

- Resolution of CKD symptoms
- Presence of adverse effects (eg, dizziness, hypoglycemia)
- Patient adherence to treatment plan using multiple sources of information

**Communicate with patient, caregivers, and CKD multidisciplinary team.*

BEYOND THE BOOK

BEYOND THE BOOK

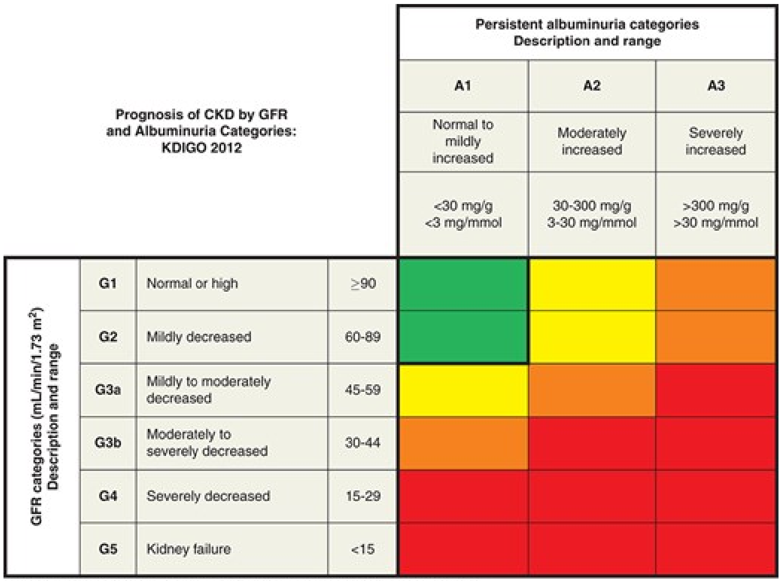
Visit The Kidney Failure Risk Equation website (available at https://kidneyfailurerisk.com/). Watch the video then practice using the Kidney Failure Risk Equation to calculate the 2-year and 5-year probability of treated kidney failure (dialysis or transplantation) for a potential patient with CKD Stage G3 to G5. The video is useful to enhance student understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

① Chronic kidney disease (CKD) is defined as abnormalities in kidney structure or function, present for 3 months or longer. Lower glomerular filtration rate (GFR) and a higher urinary albumin to creatinine ratio (ACR) are both independently associated with adverse events.[1] The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for evaluation and management of CKD classification system stages kidney disease by cause, GFR, and albuminuria. Figure 62-1 shows the KDIGO GFR and albuminuria categories along with the prognosis based on these factors.

FIGURE 62-1

KDIGO GFR and albuminuria categories and prognosis of CKD by category. To meet criteria for CKD there must be a significant reduction in GFR (categories 3a-5) or there must also be evidence of kidney damage (categories 1 and 2) for 3 months or greater. Prognosis Scale – Green: low risk (if no other markers of kidney disease, no CKD); Yellow: moderately increased risk; Orange: high risk; Red: very high risk. (CKD, chronic kidney disease; GFR, glomerular filtration rate; KDIGO, Kidney Disease Improving Global Outcomes.)



Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012				Persistent albuminuria categories Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (mL/min/1.73 m^2) Description and range	G1	Normal or high	≥90	🟩	🟨	🟧
	G2	Mildly decreased	60-89	🟩	🟨	🟧
	G3a	Mildly to moderately decreased	45-59	🟨	🟧	🟥
	G3b	Moderately to severely decreased	30-44	🟧	🟥	🟥
	G4	Severely decreased	15-29	🟥	🟥	🟥
	G5	Kidney failure	<15	🟥	🟥	🟥

The prognosis of CKD is dependent on the following factors: (a) cause of kidney disease; (b) GFR at time of diagnosis; (c) degree of albuminuria measured by ACR; and (d) presence of other comorbid conditions. Patients with any of the following should be referred to a nephrologist for evaluation and collaborative management: persistent and significant albuminuria (ACR > 100 mg/g [>11.3 mg/mmol]), progression of CKD (eg, a marked but nonacute decline in GFR), presence of a non-surgical cause of hematuria, hypertension refractory to treatment (eg, ≥4 antihypertensive agents), persistent abnormalities of serum potassium, recurrent or extensive nephrolithiasis, GFR less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), or hereditary kidney disease such as polycystic kidney disease even in the presence of normal GFR and ACR.[1]

CKD is often unrecognized and this contributes to significant morbidity, premature mortality, and a poorer prognosis when it is finally diagnosed. This chapter primarily covers the epidemiology, etiology, pathophysiology, clinical presentation, and treatment of progressive CKD. The reader is referred to Chapter 63 for a detailed discussion of management and monitoring strategies for secondary complications of CKD.

EPIDEMIOLOGY

CKD is recognized as a significant global public health problem.[2] People with CKD experience high morbidity and mortality rates with a resulting economic burden to healthcare systems due to frequent hospitalizations and the high cost of chronic dialysis and kidney transplantation. CKD affects more than 697 million individuals worldwide. In 2017, 1.2 million deaths and 35.8 million disability-adjusted life years were attributed to CKD. As a result, many countries have implemented public health initiatives to reduce the proportion of the population with CKD; increase CKD patient awareness through targeted screening programs; reduce the rate of new cases of CKD G5; and reduce mortality in persons with CKD.[2]

Diabetic kidney disease is the most frequent cause of end-stage (G5) kidney failure worldwide. Approximately 25% to 50% of all patients receiving dialysis have diabetic kidney disease.[3] In first-world countries, the leading cause of CKD is diabetes mellitus followed by hypertension.[4] It is projected that the aging population and other changes in the demographics will result in an increased incidence and subsequent increase in prevalence of Stage 5 CKD by 2030.[5] The prevalence of CKD increases with age, with the highest prevalence in individuals over 60 years mainly attributed to a decrease in estimated GFR (eGFR, less than 60 mL/min/1.73 m^2).[6] While there is some debate as to whether the eGFR decline in older individuals as a consequence of the normal physiological aging process should be considered a *disease* necessitating the label of CKD, the fact remains that patients with reduced eGFR and albuminuria suffer from worse health outcomes regardless of age.[1]

Specific racial, social, and environmental factors are important to consider when evaluating risk of progressive CKD in individual patients. Racial health disparities in CKD also exist and contribute to differing CKD rates. There is evidence for higher risk of CKD progression in patients of African, Hispanic, and Asian (South, East, and Pacific Islanders) descent and Indigenous people compared to Caucasians. This is partly explained by biological factors (eg, blood pressure) and comorbidities such as diabetes, and cardiovascular disease. However, despite a higher risk of CKD progression, there is a lower risk of mortality for patients of Asian and Hispanic descent compared to Caucasians, and a key gap in the literature is understanding why they live longer despite having a higher prevalence of comorbidities such as diabetes, cardiovascular disease, and heart failure.[7] Increased risk of CKD in high-risk ethnic groups may be tackled through closer monitoring and management of renal comorbidities such as diabetes and cardiovascular disease, for example, through albuminuria and blood pressure measurement.[7]

With regards to socioeconomic factors, the likelihood of CKD is higher in individuals with lower income and education.[8] Multiple studies conducted in the United States, Canada, and Europe have shown a strong association between low-socioeconomic status and higher incidence, prevalence and more complications related to CKD. Poverty is known to affect some of the most important social determinants of health, such as developing healthy habits, getting healthcare in a timely manner and environmental exposure to nephrotoxic agents such as lead, cadmium, and arsenic. A higher prevalence of births with low-birth weight promotes not only less development in terms of renal mass but also an increased risk of hypertension and CKD. Depression, anxiety, and increased exposure to addictions also promote the activation of the sympathetic nervous system and an increased release of cytokines that can influence the pathogenesis of kidney damage. An increased intake of sodium, sweetened beverages, and foods with phosphorus has also been reported, and the chances of receiving proper treatment to slow the progression of kidney damage are lower. A clearer understanding of the situations of vulnerable populations could allow for better public health measures to reduce the burden of kidney disease.[9]

ETIOLOGY

Susceptibility and Initiation Risk Factors

Clinical and sociodemographic risk factors for susceptibility to and initiation of CKD are listed in Table 62-1 and are useful for identifying individuals at high risk of developing CKD.[10]

TABLE 62-1

Risk Factors for Susceptibility to and Initiation of Chronic Kidney Disease

Clinical Factors
Diabetes
Hypertension
Obesity
Smoking
Autoimmune diseases, such as lupus, rheumatoid arthritis, connective tissue disease, vasculitis
Systemic infections, such as group A *streptococcus* causing post-infectious glomerulonephritis (PIGN)
Artherosclerotic vascular disease
Urinary tract infections, such as recurrent pyelonephritis
Lower urinary tract obstruction from prostatic hypertrophy, neurogenic bladder, kidney stones
Neoplasia, such as multiple myeloma, renal cell carcinoma
First degree relative with CKD
History of acute kidney injury (AKI) including recurrent episodes of dehydration
Reduction in kidney mass, such as congenital single kidney, post nephrectomy, scarring from reflux nephropathy
Exposure to nephrotoxic drugs, such as chronic use acetaminophen, NSAIDs, COX-2 inhibitors, lithium, cyclosporine, tacrolimus, contrast dyes, certain chemotherapy drugs, etc.
Pregnancy complications including edema, hypertension, proteinuria
Low-birth weight
Chronic viral infections, such as Hepatitis B and C, HIV
Hereditary polycystic kidney disease
Sociodemographic Factors
Older age
Ethnic minority status
Exposure to certain chemical and environmental conditions
Low income/education

Data from References 1,10.

Predicting Risk of Progression

KIDGO recommends that all patients with CKD be staged according to eGFR and ACR and that their prognosis be considered to help guide further testing and treatment decisions (Fig. 62-1). Estimating equations such as the kidney failure risk equation (KFRE), which incorporates urine data, sex, age, and GFR, have also been used and provide an accurate 2- and 5-year risk of progression to kidney failure for individuals with stage 3 to 5 CKD.[11] The KFRE has been widely validated in multiple international cohorts and pediatric populations and provides the best current evidence-based approach to point-of-care risk of progression to be used in combination with expert clinical judgment.[12] Risk equations may also be beneficial to help align resources with risk in assigning priority for referral to nephrologists.

Progression Risk Factors

Progression risk factors are those associated with further decline in kidney function. Persistence of the underlying initiation factors (eg, diabetes mellitus, hypertension) is the most important predictor of progressive CKD.

Diabetes mellitus

Type 2 diabetes accounts for about 90% of the 460 million people with diabetes in the world. About half of these patients will develop kidney disease.[3] The KDIGO Clinical Practice Guideline for Diabetes Management in CKD recommends an individualized HbA1c target ranging from <6.5% (0.065; 48 mmol/mol) to <8.0% (0.08; 64 mmol/mol) in patients with diabetes and CKD.[13] (Evidence level 1C) Achieving hemoglobin A_{1C} (HbA1c) targets prevents the surrogate endpoints of microalbuminuria and macroalbuminuria associated with diabetic chronic kidney disease (DIABETIC CKD).

Hypertension

The 2021 KDIGO guideline for the management of blood pressure in CKD recommends control blood pressure at all categories of CKD regardless of the underlying cause since early treatment of hypertension and achievement of target blood pressure have been demonstrated to slow the rate of progression of CKD.[14]

Albuminuria

Albuminuria is a strong independent predictor of accelerated progression of CKD and also a risk factor for CV mortality and morbidity.[1] Albuminuria remains the primary modifiable risk factor associated with CKD progression in most patients.

Smoking

Smoking is associated with kidney damage in the general population as well as in patients with diabetes and hypertension.[15] Acute reductions in GFR and an increase in urinary albumin excretion, heart rate, and blood pressure, likely secondary to nicotine exposure, have been reported.[16] Smoking is also associated with an increase in CV events in people with CKD.[1]

Obesity

Population data have demonstrated an increased risk of CKD G5 in overweight and obese subjects.[17] The risk of CKD 5 was directly related to the magnitude of obesity and remained even after adjustment for diabetes and hypertension. A body mass index (BMI) greater than or equal to 25 kg/m^2 at the age of 20 years has been associated with a threefold increase in risk of CKD compared with a BMI lower than 25 kg/m^2.[18] This association has also been shown in healthy young and middle-aged individuals without CKD or albuminuria.[19] Intentional weight loss in individuals with CKD was associated with decreases in albuminuria, systolic blood pressure, and stabilization in GFR.[20] These data suggest that weight reduction be included as part of the treatment of CKD (Table 62-2).

TABLE 62-2

Recommendations for Individuals with Chronic Kidney Disease

Nonpharmacologic

- Exercise 30 minutes five times per week [1D]
- Weight loss if BMI >25 kg/m^2 [1D]
- Smoking cessation [1D]
- Alcohol: Two standard drinks per day for men and one standard drink per day for women[a] [2D]
- If hypertension: Low-sodium diet (<2 g/day, <90 mmol/day) [1C]

Pharmacologic

- Adjust medication doses for kidney function [1A]
- Seek pharmacist or medical advice before using over-the-counter medicines or nutritional protein supplements [1B]
- Herbal medicines are not recommended [1B]
- Temporarily discontinue potentially nephrotoxic/renally excreted drugs if eGFR <60 mL/min/1.73 m^2 in patients who are acutely unwell or hypovolemic (eg, metformin, RAAS blockers, diuretics, NSAIDs/COX II inhibitors, lithium, digoxin) [1C]
- Vaccines
    - Influenza yearly [1B]
    - Pneumococcal vaccine if eGFR <30 mL/min/1.73 m^2, nephrotic syndrome, diabetes, or receiving immunosuppression. Single booster dose at year 5 [1B]
    - Hepatitis B vaccine if eGFR <30 mL/min/1.73 m^2 and risk of progression of CKD [1B]
- ASA suggested for patients at risk for atherosclerotic events unless there is an increased bleeding risk [2B]
- Avoid oral phosphate-containing bowel preparations in people with a GFR <60 mL/min/1.73 m^2 (0.58 mL/s/m^2) or in those known to be at risk of phosphate nephropathy [1A]

BMI, body mass index; CKD, chronic kidney disease; COX, cyclooxygenase; eGFR, estimated glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs; RAAS, renin–angiotensin–aldosterone system.

See Table 62-3 for definitions of evidence grading in brackets.

[a] Standard drink: 30 mL spirits, 100 mL wine, 285 mL full-strength beer, and 425 mL light beer.

Data from References 1,13

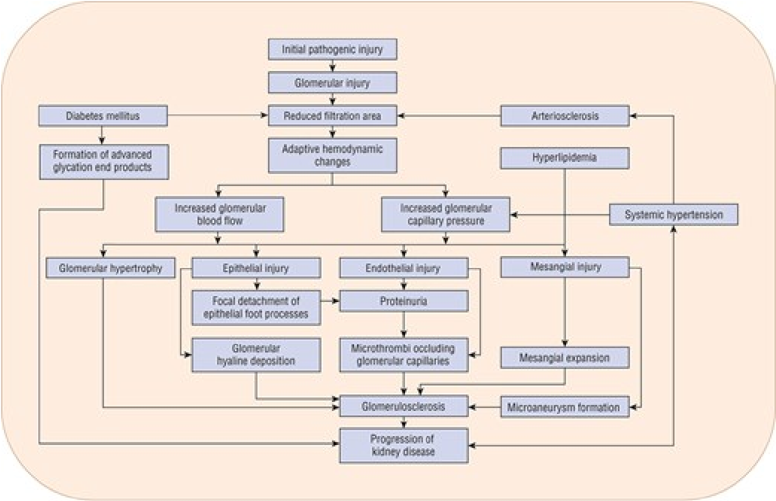
PATHOPHYSIOLOGY

Chronic Kidney Disease

Progression of CKD to more advanced stages (G4-G5) typically occurs over decades in the majority of people, with the precise mechanism of kidney damage dependent on the etiology of the disease and strongly associated with age, sex, and urine ACR. As evidenced by the variety of initiation and progression factors, kidney damage can result from an array of heterogeneous causes. Diabetic CKD is characterized by glomerular mesangial expansion while with hypertensive nephrosclerosis, the kidney's arterioles have arteriolar hyalinosis. Polycystic kidney disease is characterized by the development and expansion of renal cysts. While the initial structural damage depends on the primary disease affecting the kidney, the key elements of the pathway to ESRD are (a) loss of nephron mass, (b) glomerular capillary hypertension, and (c) albuminuria (Fig. 62-2).

FIGURE 62-2

Proposed mechanisms of progression of kidney disease.



Initial pathogenic injury
Glomerular injury
Diabetes mellitus
Reduced filtration area
Arteriosclerosis
Formation of advanced glycation end products
Adaptive hemodynamic changes
Hyperlipidemia
Increased glomerular blood flow
Increased glomerular capillary pressure
Systemic hypertension
Glomerular hypertrophy
Epithelial injury
Endothelial injury
Mesangial injury
Focal detachment of epithelial foot processes
Proteinuria
Glomerular hyaline deposition
Microthrombi occluding glomerular capillaries
Mesangial expansion
Glomerulosclerosis
Microaneurysm formation
Progression of kidney disease

Exposure to any of the initiation risk factors can result in loss of nephron mass. In response to the decrease in nephron function, the remaining nephrons compensate through the process of autoregulation. With nephron loss and the resulting reduction in perfusion pressure and GFR, renin release from the juxtaglomerular apparatus increases and converts angiotensinogen to angiotensin I, which is then converted to angiotensin II (ATII). ATII is a potent vasoconstrictor of both afferent and efferent arterioles, but it preferentially affects the efferent arterioles, leading to increased pressure within the glomerular capillaries and consequent increased filtration fraction. Initially, this compensatory action may be adaptive and beneficial; however, over time it can lead to the development of intraglomerular hypertension and hypertrophy and a further decline in the number of functioning nephrons. High intraglomerular capillary pressure impairs the size-selective function of the glomerular permeability barrier, resulting in increased urinary excretion of albumin and albuminuria. The development of intraglomerular hypertension usually parallels the development of systemic hypertension. ATII as well as aldosterone, may also mediate CKD progression through nonhemodynamic effects by increasing growth factors (eg, transforming growth factor beta [TGF-β]) and causing cellular proliferation and hypertrophy of the glomerular endothelial cells, epithelial cells, and fibroblasts ultimately resulting in further inflammation and fibrosis.[21]

Proteinuria alone may promote progressive loss of nephrons as a result of direct cellular damage. Filtered proteins such as albumin, transferrin, complement factors, immunoglobulins, cytokines, and ATII are toxic to kidney tubular cells. Studies have demonstrated that the presence of these proteins in the renal tubule leads to increased production of inflammatory and vasoactive cytokines such as endothelin and monocyte chemoattractant protein-1 (MCP-1).[22] Proteinuria is also associated with the activation of complement components on the apical membrane of proximal tubules. Intratubular complement activation may be the key mechanism of damage in the progressive proteinuric nephropathies.[22] Furthermore, these events ultimately lead to scarring of the interstitium, progressive loss of structural nephron units, and a reduction in GFR.

CLINICAL PRESENTATION

CKD is often asymptomatic, which is a reason many patients are not diagnosed with the disease until they reach CKD G4-G5 and may be near the point of requiring renal replacement therapy such as dialysis or kidney transplantation. This problem has prompted automated reporting by clinical laboratories of the eGFR as determined by the estimating equations [Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI equation)] for the purpose of identifying individuals with CKD earlier (see Chapter e60). Comprehensive screening for CKD includes analysis of eGFR and ACR (Fig. 62-1) and risk stratification for progression using the Kidney Failure Risk Equation. Clinicians must understand how to interpret the eGFR and values for urine albumin excretion to appropriately stage individuals with CKD. Chapter e60 provides a detailed discussion of the methods available for detection of urinary albumin and protein.

CLINICAL PRESENTATION: CKD Stages G1-G5

Symptoms (usually not observed until Stage G4-G5)

- Fatigue, weakness, shortness of breath, mental confusion, nausea and vomiting, bleeding, and loss of appetite, itching, cold intolerance, and peripheral neuropathies are common.

Signs

- Edema, weight gain (from accumulation of fluid), changes in urine output (volume and consistency), “foaming” of urine (indicative of albuminuria), elevated blood pressure (hypertension is a common cause and result of CKD)

Laboratory Tests

- *Decreased*: eGFR, bicarbonate (metabolic acidosis), Hb/hematocrit (Hct) (anemia), transferrin saturation (TSat) and/or ferritin (iron deficiency; note: ferritin may be increased due to inflammatory conditions), vitamin D levels, albumin (malnutrition).
- *Increased*: Serum creatinine, blood urea nitrogen, potassium, phosphorus, PTH, ACR, glucose/HbA1C (uncontrolled diabetes is a cause of CKD), low-density lipoprotein (LDL), and triglycerides.

Other Diagnostic Tests

- Urine sediment abnormalities (hematuria, red blood cell and white blood cell casts, renal tubular epithelial cells)
- Pathologic abnormalities indicating glomerular, vascular, tubulointerstitial disease, or cystic and congenital diseases
- Structural abnormalities such as polycystic kidneys, renal masses, renal artery stenosis, cortical scarring due to infarcts and pyelonephritis, or small kidneys (common in more severe CKD) detected by imaging studies (eg, ultrasound, computed tomography, magnetic resonance imaging, angiography)

TREATMENT

Desired Outcome

The overall goal of treatment is to delay or prevent progression of CKD.

General Approach to Treatment

Individuals with CKD should be evaluated frequently to assess the risk of progression of CKD, to identify the presence and causes of secondary complications and comorbid conditions, and to receive treatment for these complications prior to development of Stage G5 CKD. Many nonpharmacologic and pharmacologic recommendations can be broadly applied as part of the general approach to care for all CKD patients (Table 62-2).

② Management of CKD should be based on the KDIGO consensus guidelines (available at www.kdigo.org) which are based on evidence and expert recommendations. The available KDIGO clinical practice guidelines relevant to CKD address evaluation and management of CKD, blood pressure, diabetes, glomerulonephritis, lipid management, and hepatitis C in CKD. Table 62-3 provides a guide to the grading and strength of recommendations used in these guidelines.

TABLE 62-3

KDIGO Guidelines: Grading and Strength of Recommendations

Grade	Description	Implications for Clinicians
Level 1	"We recommend"	Most patients should receive the recommended course of action.
Level 2	"We suggest"	Different choices will be appropriate for different patients. Each patient needs help arrive at a management decision consistent with her or his values and preferences.
Grade	**Quality of Evidence**	**Meaning**
A	High	We are confident that the true effect lies close to that of the estimate of the effect.
B	Moderate	The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.
C	Low	The true effect may be substantially different from the estimate of the effect.
D	Very low	The estimate of effect is very uncertain, and often will be far from the truth.

The strength of recommendation is indicated as Level 1, Level 2, or Not Graded. The quality of the supporting evidence is shown as A, B, C, or D.

Data from Reference 1.

③ Appropriate management of CKD ideally involves a multidisciplinary approach to address the nonpharmacologic and pharmacologic interventions, dietary education, and social/financial concerns. Multidisciplinary CKD team models that have included members such as a nephrologist, nurse, dietitian, pharmacist, and social worker have demonstrated significant slowing of CKD progression, longer time to start of renal replacement therapy (dialysis or kidney transplant), and reduction in all-cause mortality.[23] Estimates in the pediatric CKD population indicate that the additional salary costs of the multidisciplinary team (pharmacist, nurse, social worker, dietician, data manager) could be recovered in one year if dialysis was delayed by one year in only 2% of patients.[24]

Drug-dosing guidelines based on the degree of kidney function should be followed, and a complete medication history of prescription and nonprescription medications, as well as herbals and nutritional supplements, should be obtained and routinely updated. Appropriate measures should also be taken for patients with CKD to decrease the risk of nephrotoxicity from radiocontrast agents, antibiotics such as aminoglycosides, as well as from nonsteroidal anti-inflammatory drugs and ACEIs (Chapter 65).[25]

Nonpharmacologic Therapy

Nonpharmacologic therapies for CKD include diet and lifestyle interventions targeted at reducing the risk for CKD progression and are outlined in Table 62-2.

Pharmacologic Therapy

Pharmacologic therapies used to slow CKD progression include drugs with demonstrated benefits to reduce albuminuria and to manage the causal factors for CKD primarily hypertension and diabetes. The next sections focus on pharmacologic therapy targeting these factors. Glomerular disease is the third leading cause of CKD and a review of the treatment strategies for glomerulonephritis is provided in Chapter e66.

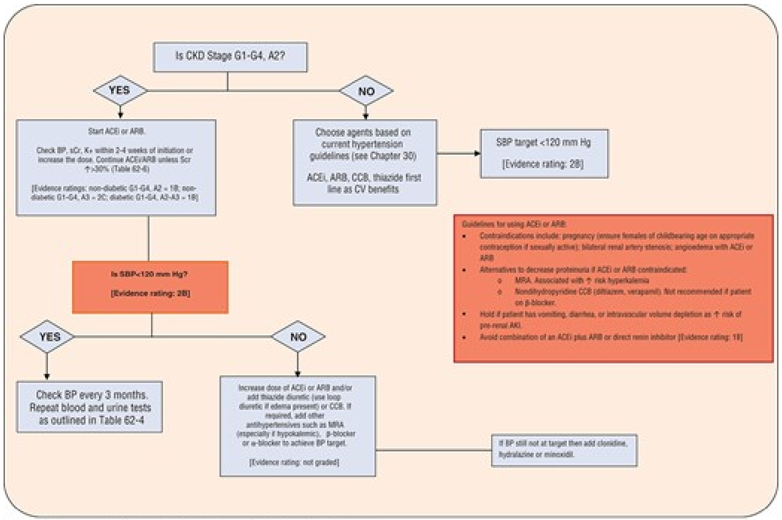
Albuminuria

ACEIs and ARBs

4 Evidence from clinical trials has confirmed the beneficial effects of ACEIs and ARBs on kidney function for patients with albuminuria. A meta-analysis has shown that the effects of ACEIs or ARBs on key CKD outcomes such as doubling of serum creatinine and prevention of progression of micro- to macroalbuminuria are equivalent and, thus, they can be used interchangeably.[26] An ACEI or an ARB should be used as first-line therapy if the patient urine albumin excretion is in category A2 or greater (ACR > 30 mg/g (>3.4 mg/mmol)) (see Fig. 62-3 and Table 62-4). The antiproteinuric effect of ACEIs and ARBs is a class effect and not specific to any one agent.[26] For patients with hypertension, the primary goal is to achieve the target blood pressure while a secondary goal is to control albuminuria. Specific dosing recommendations for ACEIs and ARBs for the treatment of albuminuria have not been established; consequently, the lowest recommended dose should be initiated and titrated up to the maximally tolerated dose. The dose is usually increased until albuminuria is reduced by 30% to 50% or side effects such as a greater than 30% increase in serum creatinine (Scr) concentration or elevation in serum potassium occur or the maximum dose for hypertension is achieved (see Table 62-5). When these drugs are used in patients with eGFR <30 mL/min per 1.73 m^2, close monitoring of serum potassium level is required. However, in patients with CKD G5 who are experiencing uremic symptoms or very high serum potassium levels (eg, $K \geq 6$ mEq/L (mmol/L)), it is reasonable to discontinue ACEI or ARB treatment temporarily with the aim of increasing eGFR to hold off starting renal replacement therapy. The STOP-ACEi Trial is testing the hypothesis that stopping treatment with ACEi, or ARB compared with continuing these treatments, improves or stabilizes renal function in patients with G4 or G5 CKD.[27] If patients exhibit a cough with an ACEI, a switch to an ARB is appropriate. Advise contraception in women of childbearing age who are receiving ACEI or ARB therapy and discontinue these agents in women who are considering pregnancy or who become pregnant as these drugs can impair fetal kidney function especially with exposure during the second and third trimester.[13] Patients should be counseled to hold ACEI or ARB on sick days (ie, vomiting or diarrhea). A thorough discussion of dose, dose titration, monitoring, and adverse effects of ACEIs and ARBs is presented in Chapter 30.

FIGURE 62-3

Treatment of hypertension in chronic kidney disease. (ACEI, angiotensin-converting enzyme inhibitor; ACR, albumin-to-creatinine ratio; AKI, acute kidney injury; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; eGFR, estimated glomerular filtration rate.)



Is CKD Stage G1-G4, A2?
YES
NO
Start ACEi or ARB.
Check BP, sCr, K+ within 2-4 weeks of initiation or increase the dose. Continue ACEi/ARB unless Scr ↑>30% (Table 62-6)
[Evidence ratings: non-diabetic G1-G4, A2 = 1B; non-diabetic G1-G4, A3 = 2C; diabetic G1-G4, A2-A3 = 1B]
Choose agents based on current hypertension guidelines (see Chapter 30)
ACEi, ARB, CCB, thiazide first line as CV benefits
SBP target <120 mm Hg
[Evidence rating: 2B]
Guidelines for using ACEi or ARB:
Contraindications include: pregnancy (ensure females of childbearing age on appropriate contraception if sexually active); bilateral renal artery stenosis; angioedema with ACEi or ARB
Alternatives to decrease proteinuria if ACEi or ARB contraindicated:
MRA. Associated with ↑ risk hyperkalemia
Nondihydropyridine CCB (diltiazem, verapamil). Not recommended if patient on β-blocker.
Hold if patient has vomiting, diarrhea, or intravascular volume depletion as ↑ risk of pre-renal AKI.
Avoid combination of an ACEi plus ARB or direct renin inhibitor [Evidence rating: 1B]
Is SBP<120 mm Hg?
[Evidence rating: 2B]
YES
NO
Check BP every 3 months. Repeat blood and urine tests as outlined in Table 62-4
Increase dose of ACEi or ARB and/or add thiazide diuretic (use loop diuretic if edema present) or CCB. If required, add other antihypertensives such as MRA (especially if hypokalemic), β-blocker or α-blocker to achieve BP target.
[Evidence rating: not graded]
If BP still not at target then add clonidine, hydralazine or minoxidil.

TABLE 62-4

Recommended Monitoring Intervals for Outcome Measure in Patients with Chronic Kidney Disease (Evidence Rating: Not Graded)

		Albuminuria Stage (based on ACR in mg/g)		
KDIGO GFR Category	**eGFR (mL/min/1.73 m^2)**	**A1: <30 mg/g (3 mg/mmol)**	**A2: 30-300 mg/g (3-30 mg/mmol)**	**A3: >300 mg/g (30 mg/mmol)**
1	≥90	12 months	12 months	6 months
2	60-89	12 months	12 months	6 months
3a	45-59	12 months	6 months	4 months
3b	30-44	6 months	4 months	4 months
4	15-29	4 months	4 months	2-3 months
5	<15	1-3 months	1-3 months	1-3 months

Blood tests to monitor: CBC, Na, K, Cl, bicarbonate, urea, creatinine, and eGFR. If DKD, add HbA1C. Fasting lipid profile at least yearly. At CKD category 3b or later: also add albumin, calcium, phosphorus, parathyroid hormone, serum iron, TIBC, and ferritin.

Urine tests to monitor: uACR (or uPCR if indicated), standard urinalysis, and urine culture and sensitivity only if symptoms suggestive of urinary tract infection.

Data from Reference 1.

TABLE 62-5

Guidelines for Monitoring Serum Creatinine and Potassium During ACEI or ARB Treatment

Adverse Drug Reaction	Monitoring Parameter	Therapeutic Adjustments	Review
↑Scr	Scr to calculate eGFR If eGFR≥60 mL/min/1.73 m^2, repeat in 4-12 weeks If eGFR 30-59 mL/min/1.73 m^2, repeat in 2-4 weeks If eGFR<30 mL/min/1.73 m^2, repeat in ≤ 2weeks	• Scr ↑0%-15%, no dose change • Scr ↑15%-30%, no dose change but repeat Scr in 2 weeks to ensure it is stable • Scr↑ 31%-50%, reduce dose and repeat Scr every 1-2 weeks until Scr within 30% of baseline • Scr↑>50%, discontinue ACE or ARB and repeat Scr every 1-2 weeks until Scr is within 15% of baseline value	If Scr ↑>30%, review for: • Causes of AKI • Hold ACEI/ARB if vomiting, diarrhea, or volume depletion • Reassess any contributing meds (eg, diuretics, NSAIDs, COX 2 inhibitors) • Consider renal artery stenosis If Scr ↑<30%, increase dose of ACEI/ARB to maximally tolerated dose.
Hyperkalemia	Serum K+ at same intervals as eGFR above	If K+>5 mEq/L (mmol/L), advise dietary K+ restriction If K+>6 mEq/L (mmol/L), consider treatment with diuretics that can lower K+ (eg, thiazide, loop) if appropriate; sodium bicarbonate tablets for patients with acidosis; potassium binders. If unable to lower K+ to <5.5 mEq/L (mmol/L), decrease or stop ACEI/ARB.	• Concurrent drugs which may cause hyperkalemia (eg, MRAs, potassium supplements) • Dietary potassium intake review preferable by a dietitian

Data from Reference 13.

The lack of response of some patients to ACEI or ARB therapy may be due to aldosterone escape from renin–angiotensin–aldosterone system (RAAS) blockade. Combination therapy with an ACEI plus an ARB or direct renin inhibitor (eg, aliskiren) produces a more complete blockade of the RAAS and results in a greater reduction in macroalbuminuria.[28] However, several trials have failed to show that dual blockade of the RAAS either slowed progression of CKD or decreased CV events.[29–32] Combination therapy in these trials was also associated with increased risks of hyperkalemia and AKI. Thus, the combination of an ACEI plus an ARB or aliskiren for the treatment of albuminuria is to be avoided (Evidence level 1B).[14]

Sodium Glucose Transport-2 Inhibitors

④ Sodium glucose transport-2 inhibitors (SGLT2i) slow progression of both Type 2 diabetic and nondiabetic proteinuric CKD with benefits that are independent of the glucose lowering effect.[33] By reducing glucose and sodium reabsorption in the proximal tubule of the kidney, these agents decrease glomerular hyperfiltration and reduce glomerular hypertension. Recent trials have demonstrated the benefits of these agents (Table 62-6). These trials have shown that SGLT2i significantly slow progression of kidney disease, reduce the need for dialysis or transplantation, and decrease mortality.[33,34] The slowing of progression of CKD equates to a gain of 15.1 years before the average CREDENCE trial patient (age 63 years; eGFR = 56 mL/min/1.83 m^2; receiving an ACEI/ARB) would reach an eGFR=10 mL/min/1.73 m^2.[34] Hence, SGLT2i could significantly reduce the need for dialysis or kidney transplant in many patients with diabetic CKD and are an exciting advance in treatment for clinicians. SGLT2i should be considered after ACEI/ARB in all patients with diabetic CKD due to Type 2 diabetes who have an eGFR ≥20 to 25 mL/min/1.73 m^2 and ACR>200 mg/g (22.6 mg/mmol). Once started, SGLT2i should be continued until dialysis or kidney transplantation. These agents are not used in patients with CKD from Type 1 diabetes due to a significantly higher risk of diabetic ketoacidosis (DKA).[35] SGLT2i may cause “euglycemic” DKA which is rare, affecting approximately one in 1,000 patients based on real world data with 40% of cases occurring during a hospital stay. Blood glucose is typically less than 252 mg/dL (14 mmol/L) (range 216-324 mg/dL (12-18 mmol/L)). There is a higher risk for euglycemic DKA in Type 2 diabetics who are receiving insulin. Most patients will present with DKA within 2 months of starting a SGLT2i with some cases occurring shortly after SGLT2i discontinuation. Most patients with SGLT2i induced DKA will have a precipitating event such as dehydration, infection, surgery, and changes in insulin dose being commonly reported.[36] Symptoms of DKA associated with SGLT2i use are similar to DKA in general, with nausea, vomiting, and abdominal pain most commonly reported. However, these patients may not present with symptoms of dehydration to the same degree as other DKA patients due to the lack of hyperglycemia.[37]

TABLE 62-6

SGLT2 Inhibitor and MRA CKD Trials

Study	**CREDENCE**	**Dapa-CKD**	**FIDELIO-DKD**
Populations			
Age (mean ±SD)	63±9.2	61.9±12.1	65.6±9.1
CKD inclusion criteria	ACR>300-5,000 mg/g + eGFR 30-<90 mL/min/1.73 m^2; Type 2 DM	eGFR 25-75 mL/min/1.73 m^2; ACR 200-5,000 mg/g (22.6-566 mg/mmol); Type 2 DM & nondiabetics included	ACR 30-<300 mg/g (3.4-34 mg/mmol) + eGFR 25-<60 mL/min/1.73 m^2 OR ACR 300-5,000 mg/g (34-566 mg/mmol) + eGFR 25-<75 mL/min/1.73 m^2; Type 2 DM
Race distribution	White 66.6%; Asian 19.9%; Black 5.15%	White 53.2%; Asian 34.1%; Black 4.4%	White 63.3%; Asian 25.4%; Black 4.7%
Mean eGFR	56.2±18.2	43.1±12.4	44.3±12.6
Median UACR (IQR)	927 (463-1833 mg/g) or 105 (52-207 mg/mmol)	965 (472-1903 mg/g) or 109 (53-215 mg/mmol)	852 (446-1634 mg/g) or 96 (50-185 mg/mmol)
Baseline medications	ACEi or ARB; no MRAs or DRIs	ACEI or ARB	ACEI or ARB
Study medication	Canagliflozin 100 mg daily	Dapagliflozin 10 mg daily	Finerenone 10 mg daily if eGFR<60 mL/min/1.73 m^2, increased to 20 mg daily if tolerated OR 20 mg daily if eGFR>60

			mL/min/1.73 m^2
Results			
Number of participants	4,401	4,304	5,674
Primary outcome	Occurrence of: ESKD (established dialysis, transplant or eGFR persistently <15 mL/min/1.73 m^2) + doubling of baseline creatinine + death from renal or CV cause (HR 0.7 (0.59-0.82)	Time to event of: ESKD (established dialysis, transplant or eGFR persistently <15 mL/min/1.73 m^2) + decline in eGFR by at least 50% + death from renal or CV cause (HR 0.61 (0.51-0.72)	Time to event of: ESKD (established dialysis, transplant or eGFR persistently <15 mL/min/1.73 m^2) + decline in eGFR by 40% from baseline + death from renal (HR 0.82 (0.73-0.93)
NNT to prevent primary outcome	22 (15-38) patients over 2.5 years	19 (14-29) patients over 3 years	29 (16-166) patients over 3 years
Key secondary outcome	CV death + hospitalization for HF (HR 0.69 (0.57-0.83)	Composite kidney outcome (50% decline, ESKD or renal death); composite CV outcome; death from any cause (HR 0.56, 0.71, 0.69 respectively)	CV death + hospitalization for HR + nonfatal MI + nonfatal stroke (HR 0.86 (0.75-0.99)
Adverse effects	Genital mycotic infections, euglycemic DKA (rare)	Genital mycotic infections, euglycemic DKA (rare)	Hyperkalemia

CREDENCE, Canagliflozin and Renal Outcomes in Type 2 Diabetes and Nephropathy; Dapa-CKD, Dapagliflozin in Patients with Chronic Kidney Disease; FIDELIO-DKD, Effect of Finerenone on Chronic Kidney Disease Outcomes in Type 2 Diabetes.

Data from References 33,34,38.

Patients at increased risk of volume depletion, mycotic genital infections (eg, vaginal yeast infections, Fournier's gangrene), women with a history of urinary tract infections, those with indwelling foley catheters may not be good candidates for this class of medications. Genital mycotic infections occur in approximately one in three patients and may be treated with topical or oral antifungals with no need to discontinue the SGLT2i.[39] The exception to this is Fournier's gangrene which requires incision and drainage and IV antibiotics. Patients should seek urgent medical care if pain, tenderness, erythema, swelling in genital or perineal area with fever and/or malaise. Patients should be counseled to hold SGLT2i on sick days (ie, vomiting or diarrhea). However, the SGLT2i groups in the clinical trials were less likely to discontinue drug versus placebo. Lower eGFR also did not result in increased adverse drug reactions and the SGLT2i group had a reduced the risk of AKI.[37] For surgery and procedures requiring one or more days in hospital, or requiring bowel preparation including colonoscopy, stop the SGLT2i at least 3 days pre-procedure (2 days prior to surgery and the day of surgery/procedure) to decrease the risk of DKA. This may require increasing other glucose-lowering drugs during that time. For day procedures (including gastroscopy), SGLT2i can be stopped on the day of procedure.[40] More details on the use of SGLT2i for the treatment of Type 2 diabetes may be found in Chapter 94.

Mineralcorticoid Receptor Antagonists (MRA)

The concept of aldosterone escape has led to the search for other drug combinations to further suppress the RAAS to improve kidney outcomes. A Cochrane systematic review examined the addition of the MRA spironolactone to an ACEI or ARB in patients with CKD Stage G1-G4.[41] Spironolactone significantly reduced albuminuria and blood pressure but doubled the risk of hyperkalemia and significantly increased the risk of gynecomastia.

However, it is unknown whether adding spironolactone or eplerenone to ACEI or ARB will reduce the risk of major CV events or ESKD as a large efficacy trial in DIABETIC CKD has never been performed.[42]

Finererone is a novel, more selective, nonsteroidal MRA. The FIDELIO-DKD trial examined kidney and cardiovascular outcomes in patients with CKD due to Type 2 diabetes (Table 62-6).[38] The risk of hyperkalemia was higher in patients receiving finerenone with an absolute risk increase (ARI) of 12% for serum potassium greater than 5.5 mEq/L (mmol/L) and 3% for serum potassium greater than 6 mEq/L (mmol/L). More patients in the finerenone group needed potassium binding agents for hyperkalemia (307 vs 184 in placebo).[3] Finerenone, unlike spironolactone, is not a blood pressure lowering drug as mean systolic blood pressure decreased by 2 mm Hg. The patient centric quality of life results of this trial have not been reported yet.[38] Only 4.4% of patients were also on an SGLT2i, therefore, a study examining finerenone in combination with SGLT2i plus ACEI/ARB is still needed. However, finerenone could be considered in patients who cannot tolerate SGLT2i.

Nondinydropyridine Calcium Channel Blockers

Nondihydropyridine calcium channel blockers (diltiazem and verapamil) have yielded beneficial effects on albuminuria, although not as profoundly as ACEIs.[43] The postulated mechanisms for this decrease in kidney injury include suppression of glomerular hypertrophy, inhibition of platelet aggregation, and a decrease in salt accumulation. These agents have been used to reduce albuminuria in combination with an ACEI or ARB even though there are limited data to support this strategy. In general, nondihydropyridine CCBs should be considered third-line antiproteinuric drugs when an ACEI/ARB and SGLT2 inhibitor is contraindicated or not tolerated (Fig. 62-3).[57]

Hypertension

Figure 62-3 provides an algorithm for recommended blood pressure goals based on the degree of albuminuria present and the choice of antihypertensive agent.

The Systolic Blood Pressure Intervention Trial (SPRINT) is the largest trial testing BP targets in CKD. SPRINT assessed whether a lower systolic blood pressure goal of less than 120 mm Hg versus a target of less than 140 mm Hg was desirable.[44] In the 2,646 participants with CKD, the composite renal outcome of a decrease in eGFR of 50% or more or the need for chronic dialysis or kidney transplantation was not significant over the 3.3 years duration of this trial but CV events and all-cause mortality were reduced.[14] Within the CKD subgroup, SPRINT reported no significant difference in serious adverse events. There were increased risks for hypokalemia and hyperkalemia, presumably because of the greater use of antihypertensive medications. Intensive BP lowering increased the risk of AKI in people with moderate CKD (eGFR<45 mL/min/1.73 m^2) and advanced age (>75 years), but the episodes were infrequent and tended to be mild and reversible.[14] There were potential harms to all participants (with and without CKD) in the intensive systolic blood pressure group that included significantly increased risks of syncope, hypotension, electrolyte abnormalities, AKI, and CKD progression.[44] However, the CV and mortality benefits outweigh the risks of harm even in frail and elderly patients.[14]

A SBP target <120 mm Hg may be appropriate in patients who achieve SBP in the 120s without requiring a high number of antihypertensives and who are not experiencing adverse effects of therapy. It is reasonable to consider a change in medications or less-intensive therapy if the patient is symptomatic or BP is excessively low (eg, SBP <100 mm Hg).[14] In practice, adoption of this recommendation in a population of patients with CKD will result in a median SBP around 120 mm Hg, meaning that 50% of patients will have SBP greater than 120 mm Hg.[14] The mean achieved SBP in SPRINT was 121.4 mm Hg.[44] Patients prescribed ACEI/ARBs or diuretics who are targeting an SBP below 120 mm Hg need to be reliable and able to follow instructions to hold these medications when they are unable to maintain adequate fluid intake (eg, vomiting/diarrhea) due to the risk of AKI. The adoption of an SBP target less than 120 mm Hg is an ideal topic for shared decision-making between individual patients and clinicians. There is likely to be marked variability in how individual patients weigh and value the potential benefits and harms of intensive BP control. This may vary with age, culture, number of drugs (both BP-lowering and other drugs), and other factors.[14]

Diabetes

Patients with diabetes should be screened annually for CKD starting at the time of diagnosis of type 2 diabetes and 5 years after the diagnosis of type 1 diabetes by ordering a serum creatinine, eGFR, and a urine albumin-to-creatinine ratio (ACR).[13]

The management of diabetes in patients with CKD includes reduction of albuminuria and achievement of desired blood pressure and HbA1c (Chapter 94). An individualized HbA1c target ranging from <6.5% (0.065; 48 mmol/mol) to <8.0% (0.08; 64 mmol/mol) is recommended[13] (Evidence Level 1C). Clinicians may consider a target greater than 7% (0.07; 53 mmol/mol) if there is a risk of hypoglycemia, multiple comorbidities, lack of hypoglycemia symptoms or awareness, or limited life expectancy.[13,45] A lower HbA1C target (eg, <6.5% [0.065; 48 mmol/mol] or <7% [0.07; 53 mmol/mol]) is preferred in patients where prevention of complications is the main goal. It should be noted that HbA1c measurements are based on an assumed red blood cell life span of 90 days. In later stage, CKD G4-G5, the red blood cell life span is decreased, so HbA1c values may be falsely low.[45] Hence, in patients with CKD, the HbA1c should be interpreted along with the patient's home blood glucose readings when assessing diabetic control. It is also important to note that patients with CKD G4-G5 are at higher risk of developing hypoglycemia because of the reduction in metabolism of insulin by the kidney as GFR declines. As a result, these patients may require reduced doses of oral or injectable hypoglycemic agents and using agents associated with a lower risk of hypoglycemia (metformin, SGLT2i, GLP-1 receptor agonists, DPP-4 inhibitors). Metformin is still considered a first-line agent in individuals with type 2 diabetes and CKD[14] (Evidence level 1B). As previously discussed, most patients with CKD due to Type 2 diabetes should also be treated with an SGLT-2 inhibitor if eGFR is greater than or equal to 20 to 25 mL/min/1.73 m^2 and the patient is already receiving an ACEI or ARB. Metformin can be initiated and/or continued in individuals with an eGFR greater than or equal to 30 mL/min/1.73 m^2. The metformin dose should be reduced to 500 mg once or twice daily in patients with an eGFR between 30 and 44 mL/min/1.73 m^2.[46] Metformin is contraindicated in individuals with an eGFR less than 30 mL/min/1.73 m^2 due to the rare but serious risk of lactic acidosis and should be temporarily discontinued before administering contrast agents for imaging studies. Monitor patients for vitamin B12 deficiency when they are treated with metformin for more than 4 years, as metformin interferes with intestinal vitamin B12 absorption.[13] Dose adjustments or avoidance of other renally eliminated hypoglycemic agents may also be necessary; the dosing, monitoring, and goals of therapies to treat diabetes mellitus are detailed in Chapter 94.

Evaluation of Therapeutic Outcomes

Frequency of laboratory and urine testing based on CKD category and degree of albuminuria as defined by KDIGO are shown in Table 62-4. The monitoring necessary for patients with hypertension and diabetes is the same in the CKD population as it is in the non-CKD population.

CONCLUSION

The prevalence of CKD continues to increase especially in high-risk populations. Although efforts to delay progression of CKD, including prudent use of ACEI/ARB and SGLT2i in diabetic patients are paramount, measures to diagnose and manage the associated secondary complications and comorbid conditions early in the course of the disease are also essential.

A multidisciplinary team structure is a rational approach to effectively design and implement individual patient care plans often required in the CKD population given the extensive nonpharmacologic and pharmacologic interventions. Pharmacists are well positioned to actively participate in the chronic disease and medication management of ambulatory CKD patients as well as those who are hospitalized.

ABBREVIATIONS

ACEI	angiotensin-converting enzyme inhibitor
ACR	urinary albumin-to-creatinine ratio
AKI	acute kidney injury
ARB	angiotensin receptor blocker
ATII	angiotensin II
CCB	calcium channel blocker

CKD	chronic kidney disease
CKD-EPI equation	Chronic Kidney Disease Epidemiology Collaboration equation
CREDENCE	Canagliflozin and Renal Outcomes in Type 2 Diabetes and Nephropathy
CV	cardiovascular
CVD	cardiovascular disease
Dapa-CKD	Dapagliflozin in Patients with Chronic Kidney Disease
DKA	diabetic ketoacidosis
eGFR	estimated glomerular filtration rate
ESRD	end-stage renal disease

SELF-ASSESSMENT QUESTIONS

1. Risk factors for the development of CKD include which of the following:

    A. Family history of CKD and diabetes

    B. Obesity and hypertension

    C. Low-birth weight and low education level

    D. All of the above

2. A 51-year-old female with an eGFR of 37 mL/min/1.73 m^2 and a urinary albumin-to-creatinine (ACR) ratio of 20 mg/g (2.3 mg/mmol) would be classified in which albuminuria and KDIGO category of CKD?

    A. G3a, A1

B. G3a, A2

C. G3b, A1

D. G3b, A2

3. A 44-year-old female with a history of CKD due to type 2 diabetes presents to your primary care clinic. Her most recent ACR is 113 mg/g (12.8 mg/mmol), her eGFR is 44 mL/min/1.73 m^2, and blood pressure is 137/88 mm Hg. She is on chlorthalidone 12.5 mg po daily as her only antihypertensive drug. Which one of the following recommendations is most appropriate?

   A. No changes, blood pressure is at target

   B. Start dapagliflozin 10 mg po daily

   C. Start ramipril 2.5 mg po daily

   D. Start amlodipine 5 mg po daily

4. Patients with CKD who have severe vomiting, diarrhea, or are dehydrated should be instructed to hold which of the following medications?

   A. Enalapril

   B. Metformin

   C. Dapagliflozin

   D. All of the above

5. Hypertensive patients with CKD should limit dietary sodium to which of the following?

   A. <1 g/day

   B. <1.5 g/day

   C. <2 g/day

   D. <2.5 g/day

6. According to the KDIGO guideline, what is the blood pressure target in a patient with CKD and a urinary albumin-to-creatinine (ACR) of 22 mg/g (2.5 mg/mmol)?

   A. SBP<120 mm Hg

   B. SBP <130 mm Hg

   C. SBP<135 mm Hg

   D. SBP <140 mm Hg

7. A 67-year-old female with urinary albumin-to-creatinine ratio (ACR) of 55.4 mg/g (6.3 mg/mmol), a serum potassium of 4.5 mEq/L (mmol/L), and an eGFR of 38 mL/min/1.73 m^2 is started on irbesartan 75 mg po once daily. The serum creatinine and potassium levels should be monitored at what time point after initiation of therapy?

   A. In 2 days

   B. In 1 week

C. Within 2 to 4 weeks

D. Within 4- to 2 weeks

8. A patient with type 2 diabetic CKD is receiving candesartan 32 mg po daily. Their eGFR is 27 mL/min/1.73 m^2 and ACR is 221 mg/g (25 mg/mmol) despite the ARB. Which class of medications should be considered next?

   A. MRA

   B. SGLT2i

   C. ACEI

   D. Nondihydropyridine CCB

9. Patients receiving SGLT2i should be counseled on which of the following adverse effects?

   A. Risk of increased mycotic genital infections

   B. Risk of euglycemic DKA

   C. Rick of urinary tract infections

   D. All of the above

10. A patient receiving canagliflozin 100 mg po daily for treatment of diabetic CKD returns to clinic and their eGFR has decreased to 12 mL/min/1.73 m^2. What should be done with their canagliflozin?

    A. Discontinue canagliflozin

    B. Decrease dose to 50 mg po daily

    C. Continue same dose

    D. Switch to dapagliflozin

11. ACEI or ARBs should be held when which of the following occurs?

    A. Stage G5 with uremic symptoms

    B. Serum potassium >6 mEq/L (mmol/L)

    C. Scr increases >50%

    D. All of the above

12. Contraindications to the use of ACEI or ARB include which of the following?

    A. Pregnancy or wanting to become pregnant

    B. Bilateral renal artery stenosis

    C. Cough

    D. Both A and B

13. Finerenone is a treatment option for patients with diabetic CKD. Which of the following characteristics best describe this drug?

A. Associated with hyperkalemia

B. Lowers blood pressure

C. Reduces CV events

D. Both A and C

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** All of the factors listed increase risk for the development of CKD. See Table 62-1 for more information.

2. **C.** The patient would be classified as G3b, A1. See Fig. 62-1.

3. **C.** Patient is in Stage G3b, A2, so starting an ACEI or ARB is recommended. The SBP target for most CKD patients based on the SPRINT trial is <120 mm Hg. An ACEI or ARB should be started and titrated to the maximally tolerated dose before adding an SGLT2i to treat her diabetic CKD. See Fig. 62-3 for more information.

4. **D.** Sick day medications include ACEI/ARBs, diuretics, metformin, SGLT2i, sulfonylureas, NSAIDs, or COX 2 inhibitors.

5. **C.** See information related to nonpharmacologic therapies in Table 62-2.

6. **A.** The 2021 KDIGO Blood Pressure in CKD guideline now suggests a target SBP<120 mm Hg in most patients based on the results from the SPRINT trial; however, individual patient characteristics and patient preference should be used before targeting intensive therapy. See Fig. 62-3 for more information.

7. **C.** If eGFR 30 to 59 mL/min/1.73 m^2, repeat Scr and serum potassium in 2 to 4 weeks. See Table 62-5 for more information.

8. **B.** SGLT2i should be considered in patients with diabetic CKD due to Type 2 diabetes and maximally tolerated doses of ACEI or ARB with ACR>200 mg/g (22.6 mg/mmol) and eGFR ≥20 to 25 mL/min/1.73 m^2.

9. **D.** SGLT2i treatments have been associated with all of the adverse effects listed.

10. **C.** Once started, SGLT2i should be continued until dialysis or kidney transplantation as was done in the CREDENCE and Dapa-CKD trials (see Table 62-5).

11. **D.** It is reasonable to discontinue ACEI or ARB treatment temporarily with the aim of increasing eGFR to hold off starting renal replacement therapy in patient with Stage G5 with uremic symptoms. In patients with K>6 mEq/L (mmol/L), the ACEI or ARB should be held until the K+ is treated and a K+ <5.5 mEq/L (mmol/L) is consistently achieved (see Table 62-6). If Scr increase is >50%, the ACEI/ARB should be stopped (see Table 62-6).

12. **D.** Pregnancy is a contraindication as ACEI and ARB therapy can affect the developing fetus' kidneys, especially in the second and third trimesters. Bilateral renal artery stenosis will cause the eGFR to decrease dramatically since angiotensin II constricts the efferent arteriole and blocking it will cause the efferent arteriole to dilate. Renal artery stenosis patients rely upon that efferent constriction to maintain normal glomerular pressures for filtration (Figure 62-3). Cough is a side effect of ACEI inhibitors due to the accumulation of bradykinin but this side effect is not associated with ARBs.

13. **D.** Finerenone is a nonsteroidal, more selective MRA but is still associated with hyperkalemia. It is not an effective blood pressure lowering agent as patients in the FIDELIO-DKD trial exhibited reductions in SBP of 2 mm Hg. FIDELIO-DKD also showed that this drug lowered CV events as a secondary endpoint (see Table 62-5).

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 63: Chronic Kidney Disease: Management of Secondary Complications

Joanna Q. Hudson

KEY CONCEPTS

KEY CONCEPTS

①Chronic kidney disease (CKD) affects many other organ systems leading to secondary complications. The most common complications include fluid and electrolyte disorders, anemia, mineral and bone disorder, metabolic acidosis, and increased incidence of cardiovascular disease.

②Anemia of chronic kidney disease (CKD) is multifactorial with loss of erythropoietin synthesis by the kidney, iron deficiency, and chronic inflammation all implicated.

③CKD-mineral and bone disorder (CKD-MBD) includes abnormalities in parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23), phosphorus, calcium, vitamin D, and bone turnover, and contributes to soft-tissue and extravascular calcifications.

④Guidelines from the Kidney Disease: Improving Global Outcomes (KDIGO) provide information to assist healthcare providers in clinical decision making and the design of appropriate therapy to manage complications of CKD.

⑤Patient education, an interdisciplinary team, and shared decision-making play critical roles in the appropriate management of complications of CKD.

⑥Management of anemia includes administration of erythropoiesis-stimulating agents (ESAs) and regular iron supplementation to maintain the target hemoglobin concentration and prevent the need for blood transfusions. There is a higher risk of cardiovascular events when ESAs are used to target hemoglobin values greater than 11 g/dL (110 g/L; 6.83 mmol/L).

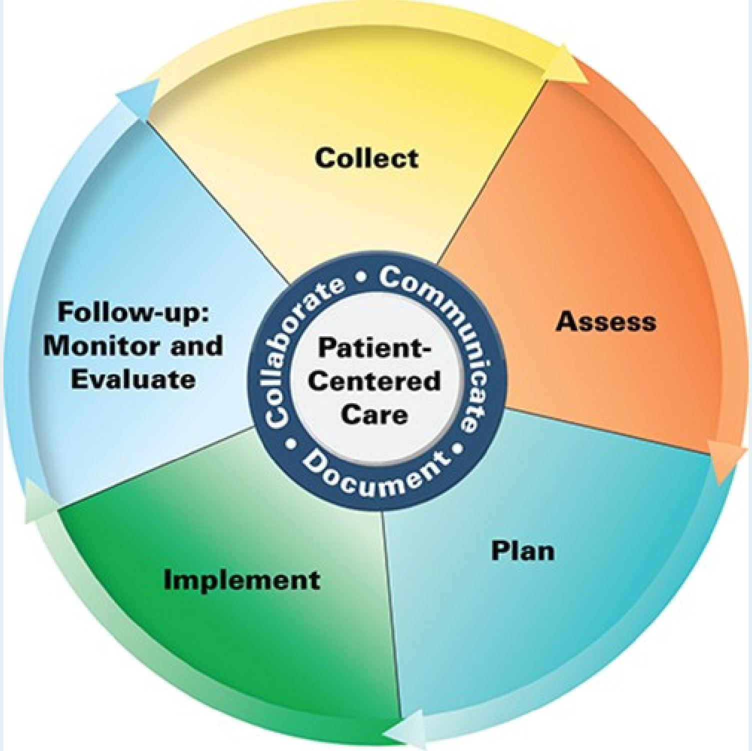
⑦Management of CKD-MBD includes dietary phosphorus restriction, phosphate-binding agents, activated vitamin D supplementation, and calcimimetic therapy to achieve KDIGO targets.

⑧Initiation of statins for primary prevention of hyperlipidemia in patients receiving dialysis is not recommended due to a lack of benefits from randomized controlled trials and meta-analyses, while benefit still may exist in those with non-dialysis dependent CKD.

⑨CKD-associated pruritus is a secondary complication that significantly affects patients' quality of life and has limited treatment options. Difelikefalin is a selective kappa opioid receptor agonist with antipruritic effects approved for pruritus in hemodialysis patients and is the only approved treatment option.

PATIENT CARE PROCESS

Patient Care Process for Secondary Complications of Chronic Kidney Disease (CKD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, CKD stage [see Chapter 62], medication allergies)
- Past medical history
- Social history (eg, smoking), family/friend supports
- Dietary intake (eg, phosphate-containing foods/sources, iron sources, sodium intake)
- Current medications including OTC medications, herbals, dietary supplements
- Objective data:
    - Blood pressure, heart rate, weight
    - Labs as defined under “Assess”

Assess

- CKD stage (see Chapter 62 for staging criteria)
- Reported symptoms: see Clinical Presentation for signs and symptoms of secondary complications
- Serum potassium concentration - assess frequently in CKD stage 4, 5 and end-stage kidney disease (ESKD)
- Volume status—peripheral and pulmonary edema versus hypovolemia (may need to alter diuretic regimen)
- Hemoglobin concentration (see Table 63-2 for ESA initiation)
- Iron indices (transferrin saturation and ferritin) for patients on an ESA, assess transferrin saturation (TSAT) and ferritin at least every 3 months and assess when clinically indicated (eg, following blood loss)

- Concentrations of calcium, albumin (to calculate corrected calcium), phosphorus, and parathyroid hormone (PTH) (see Table 63-6)
- Insurance coverage of medications, current out of pocket cost of medications
- Medication adherence
- Other recommendations as outlined in Chapter 62

Plan

- Drug therapy recommendations, including dose, route, frequency, and duration
- Dietary recommendations (consider sodium, potassium, phosphorus and fluid intake).
- Monitoring parameters, including frequency and timing of follow-up
- Patient education, including purpose of new or changed treatment, lifestyle modifications, medication administration (eg, timing of phosphate binders with meals), injection technique
- Self-monitoring for resolution of symptoms
- Referrals to other providers when appropriate (eg, clinical pharmacist, dietitian, nephrologist, nephrology nurse, social worker, endocrinologist)

Implement*

- Provide patient education on all elements of the treatment plan
- Use motivational interviewing strategies to maximize adherence
- Schedule follow-up labs and appointment, adherence assessment

Follow-up: Monitor and Evaluate

- Resolution of symptoms
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information

**Communicate with patient, caregivers, and CKD multidisciplinary team.*

BEYOND THE BOOK

BEYOND THE BOOK

Read and evaluate the case presented in Chapter 56—End-Stage Kidney Disease: Urine Trouble Level II. In: Schwinghammer TL, Koehler JM, Borchert JS, Slain D, Park SK. eds. *Pharmacotherapy Casebook: A Patient-Focused Approach*, 11e. Mcgraw Hill; 2020. Available at https://accesspharmacy.mhmedical.com/content.aspx?bookid=2868&sectionid=242182546.

This activity is useful to enhance student understanding regarding the COLLECT, ASSESS, PLAN, and IMPLEMENT steps in the patient care process.

INTRODUCTION

① Chronic kidney disease (CKD) affects many organ systems and processes leading to secondary complications. While the primary goal is to prevent CKD progression and the resultant complications (see Chapter 62 for a more in-depth discussion of CKD progression and management), ultimately many individuals progress to the more advanced stages of CKD (CKD G4 – end-stage kidney disease, ESKD). The most common complications of CKD include fluid and electrolyte disorders (hypervolemia, hyperkalemia), anemia, mineral and bone disorder, metabolic acidosis and increased incidence of cardiovascular disease (CVD). Complications of CKD are frequently unrecognized or are inappropriately managed, and for many patients, this contributes to significant morbidity, premature mortality, or a poorer prognosis if and when they require renal replacement therapy. This chapter primarily covers the pathophysiology and treatment of anemia, CKD-MBD, select cardiovascular complications, and CKD-associated pruritus in adult patients with CKD. The reader is referred to Chapters 68, 70, and 71 for a more detailed discussion of management and monitoring strategies for CKD patients with hypervolemia, hyperkalemia, and metabolic acidosis, respectively. A comprehensive list of complications of advanced CKD is provided in Table 63-1.

TABLE 63-1

Complications of Chronic Kidney Disease[a]

Organ System or Complication	Clinical Manifestations[a]
Amyloidosis	Accumulation of β_2-microglobulin Carpal tunnel syndrome
Cardiovascular disease	Atherosclerosis-related complications (arrhythmias, heart failure, myocardial infarction, stroke)
Endocrine	Hypoglycemic episodes (result of decreased degradation of insulin by the kidney)
Gastrointestinal	Nausea, vomiting, anorexia (from uremia) Delayed gastric emptying Gastroesophageal reflux GI bleeding
Hematologic	Anemia Bleeding diathesis Platelet dysfunction
Hyperkalemia	Arrhythmias/ECG changes Metabolic acidosis Muscle weakness or paralysis
Hypervolemia	Edema Heart failure Hypertension
Immune disorders	Impaired cell-mediated immunity Lymphopenia
Metabolic acidosis	Bone disease

	Hyperkalemia Reduced respiratory reserve Skeletal muscle catabolism
Mineral and bone disorder	Bone fractures Calciphylaxis
Neurologic	Peripheral neuropathies Restless leg syndrome Uremic encephalopathy
Protein–energy wasting	Malnutrition
Uremic pruritus	Generalized itching predominantly of back, face, and extremity used for vascular access, but may affect any area (May be more severe during or immediately after hemodialysis)

ECG, electrocardiogram.

[a] Not all inclusive.

EPIDEMIOLOGY

Anemia of Chronic Kidney Disease

As a common complication of CKD, anemia prevalence increases with age in individuals with non-dialysis (ND) CKD with reports of 50% prevalence in older Medicare patients (aged 66-85 years) and 28% in younger individuals (aged 18-63 years).[1] This prevalence increases as CKD progresses with estimates of 44% in CKD G3 increasing to 73% in CKD G5 for the older individuals and 22% increasing to 54% in the younger individuals. Despite the fact that anemia is a well-recognized complication of CKD, management in suboptimal, particularly in the ND-CKD population where patients who meet criteria for treatments including ESAs and iron often do not receive an intervention.[2] This is supported by the fact that the average hemoglobin (Hb) among incident (new) ESKD patients in the United States in 2018 was 9.3 g/dL (93 g/L; 5.77 mmol/L) with levels less than 9 g/dL (90 g/L; 5.59 mmol/L) in many areas throughout the United States. Only 14.6% of incident patients had received an erythropoiesis stimulating agent (ESA) prior to ESKD.[3] Furthermore, iron deficiency is present in more than half of ND-CKD patients and up to 25% of dialysis patients, in part, due to the fact that iron supplementation is not a standard treatment approach for ND-CKD patients.[4] For prevalent dialysis patients (on dialysis for at least 90 days), the majority of patients maintain Hb levels between 10 and 11.9 g/dL (100 and 119 g/L; 6.21 and 7.39 mmol/L), due in large part to protocol driven approaches that lead to ESA and iron use.[5] This does not negate the fact that suboptimal anemia management at initiation of dialysis is associated with increased mortality, even if corrected in the subsequent months after dialysis initiation.[6] Anemia of CKD is also associated with increased morbidity with greater likelihood of hospitalization, cardiovascular (CV) disease, cognitive impairment, and decreased quality of life.[7]

Chronic Kidney Disease–Related Mineral and Bone Disorder

CKD-MBD collectively includes abnormalities in parathyroid hormone (PTH), calcium, phosphorus, active vitamin D, and fibroblast growth factor 23 (FGF23) and is considered one of the most common CKD related secondary complications with significant implications on patient morbidity and mortality. Abnormalities in these parameters, particularly elevations in PTH and FGF23, may be observed in earlier stages of CKD (stage G3) with hyperphosphatemia and calcium abnormalities more prevalent as kidney function declines to stage G4.[8,9] Data regarding prevalence are limited in the non-dialysis CKD population. Based on data from dialysis patients such the Dialysis Outcomes and Practice Patterns Study (DOPPS) approximately 24% of ESKD patients on HD have hyperparathyroidism (defined as a PTH > 600 pg/mL [ng/L; 64.2 pmol/L]) and 43% have phosphorus above goal (phosphorus > 5.6 mg/dL [1.81 mmol/L]).[5] CKD-MBD worsens as kidney function declines with more resistant disease associated with worsening kidney function.[9] Severity of this secondary complication is also indicated by control of associated parameters (PTH, albumin correct calcium and phosphorus) and use of pharmacologic therapy. Based on data from US hemodialysis patients, approximately 70% of patients had at least one parameter out of control PTH (> 600 pg/mL [ng/L; 64.2 pmol/L], corrected calcium > 10.2 mg/dL [2.55 mmol/L], serum phosphorus > 5.5 mg/dL [1.78 mmol/L]).

ETIOLOGY AND PATHOPHYSIOLOGY

Anemia of Chronic Kidney Disease

② The primary cause of anemia of CKD is a relative deficiency in production of erythropoietin by interstitial fibroblasts in the outer renal cortex and medulla of the kidney where approximately 90% of production occurs (the remainder occurs in the liver). Erythropoietin is a glycoprotein hormone that stimulates erythropoiesis (red blood cell production) by binding to receptors on early erythroid progenitor cells, burst-forming units, and colony-forming units in the bone marrow, thus, preventing apoptosis and allowing cell division and maturation into mature red blood cells. In individuals with normal kidney function, plasma concentrations of erythropoietin increase exponentially in response to hypoxia to promote erythropoiesis; however, this response is lost as kidney disease progresses.[10]

Impaired oxygen sensing in the kidneys leads to disrupted signaling of specific hypoxia inducible factors (HIFs). HIF is a transcription factor composed of oxygen regulated α subunits (HIF-1α and HIF-2α) and a β subunit. The β subunit is present consistently in the HIF complex and binds with one of the three isoforms of the α subunit to induce expression of target genes depending on the complex formed. Erythropoietin gene transcription for all hypoxia-induced genes is initiated by HIF-α with the HIF-2α subunit being the main subunit involved in erythropoietin production and iron transport. In the presence of normal oxygen levels, an enzyme known as HIF-prolyl hydroxylase (HIF-PH) is activated and causes HIF-α to be hydroxylated which leads to its degradation and no stimulation of erythropoietin production by erythropoietin producing cells. In hypoxic conditions, the HIF-PH enzyme is inactive allowing HIF-α to translocate to the cell nucleus where it forms a heterodimer with the β subunit causing activation of gene transcription to increase erythropoietin production, promote iron absorption and transport, and decrease hepcidin levels. This is a nicely regulated system that is altered in CKD. With CKD, oxygen consumption in the kidneys is decreased due to disease-related changes (Fig. 63-1). Despite the fact that hypoxia is present systemically, the erythropoietin producing cells do not detect the extent of hypoxia since there is sufficient oxygen in the immediate environment (in the kidney relative to oxygen needs). This results in a disruption in HIF signaling and a relative deficiency in erythropoietin production.[11–13]

FIGURE 63-1

HIF activity under normoxia and hypoxia. Under normoxia (normal oxygen conditions) oxygen binds with the HIF-PH enzyme to form a complex with HIF-α which is then degraded. With hypoxia (reduced oxygen conditions) the HIF-PH enzyme is inactive and the HIF-α subunit can translocate to the cell nucleus where it forms a heterodimer with the β subunit. This leads to gene transcription and expression of multiple genes resulting in increased endogenous erythropoietin production, decreased hepcidin, and improved iron absorption, mobilization, and transport. (HIF-PH, Hypoxia inducible factor prolyl hydroxylase enzyme; HRE, HIF responsive element, Pro, proline.) *(Reprinted, with permission, from Locatelli F, Fishbane S, Block GA, MacDougall IC. Targeting hypoxia-inducible factors for thetreatment of anemia in chronic kidney disease patients. Am J Nephrol. 2017;45:187–199.)*

In addition to impaired erythropoietin production, iron deficiency is common in individuals with advanced kidney disease (ie,, CKD stages G4, G5, and ESKD) due to decreased gastrointestinal (GI) absorption of iron, inflammation, frequent blood testing, blood loss from hemodialysis (HD) for patients with ESKD, and increased iron demands from erythropoiesis stimulating agent (ESA) therapy when treatment is initiated. Iron deficiency is the leading cause of resistance to ESAs and the reason frequent iron supplementation is necessary.[10,14] Hepcidin, a hormone produced by the liver, is a primary regulator of iron homeostasis. This hormone directly binds to and inhibits the protein ferroportin that transports iron out of storage cells and into circulation. When iron stores are high, hepcidin production is increased and results in a decrease in intestinal iron absorption, impairment of iron recycling from macrophages, and decreased mobilization of stored iron from hepatocytes. Hepcidin production is also induced by inflammation or infection. As a result, the increase in hepcidin in inflammatory conditions leads to sequestering of iron, decreased iron absorption, and ineffective red blood cell production. Conversely, hepcidin production is decreased when iron stores are low. The fact that hepcidin plays such a role in iron regulation has prompted the development of agents to target hepcidin and potentially alter iron transport.[15]

Additional factors contributing to the development of anemia of CKD are the decreased red cell life span (from the normal of 120 days to approximately 60 days in individuals with CKD 5D), the effects of accumulation of uremic toxins and inflammatory cytokines, and vitamin B_{12} and folate deficiencies.

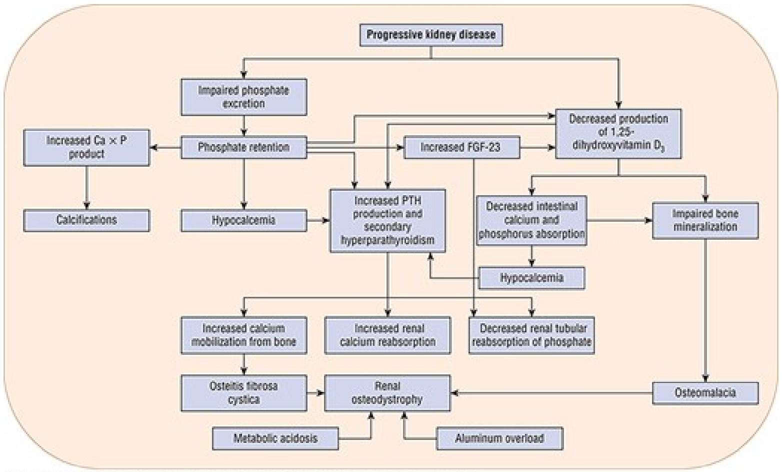
Chronic Kidney Disease–Related Mineral and Bone Disorder

③Disorders of mineral and bone metabolism are common in the CKD population and include abnormalities in PTH, calcium, phosphorus, vitamin D, fibroblast growth factor-23 (FGF-23), bone turnover, as well as soft-tissue calcifications. These abnormalities have been described as characteristics of secondary hyperparathyroidism (sHPT) and renal osteodystrophy (ROD). The term CKD-MBD encompasses these abnormalities in mineral and bone metabolism as well as associated calcifications.

The pathophysiology of CKD-MBD is complex (Fig. 63-2). Calcium and phosphorus homeostasis is mediated through the effects of PTH, 1,25-dihydroxyvitamin D_3 (calcitriol), and FGF-23 on bone, the GI tract, kidney, and the parathyroid gland. As kidney function declines, there is a decrease in phosphate elimination, which results in hyperphosphatemia and a decrease in serum calcium concentration. Hypocalcemia is the primary stimulus for secretion of PTH by the parathyroid glands. Hyperphosphatemia also increases PTH synthesis and release through its direct effects on the parathyroid gland and production of prepro-PTH messenger RNA.[16] In an attempt to normalize ionized calcium, PTH increases calcium reabsorption by the distal tubules and decreases phosphate reabsorption in the proximal tubules of the kidney (at least until the GFR falls to less than 30 mL/min/1.73 m^2 [0.29 mL/s/m^2]) and also increases calcium mobilization from bone. FGF-23 production in bone also increases in response to high phosphate levels and increased PTH and promotes phosphate excretion by the kidney. The result is a relative normalization of calcium and phosphorus, at least in the early stages of CKD; however, this occurs at the expense of an elevated PTH and FGF-23 ("the trade-off hypothesis"). The increase in PTH is most notable when GFR is less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2) (CKD G3a and higher) and worsens as kidney function further declines.[16] With advanced kidney disease, the kidney fails to respond to PTH or to FGF-23 and abnormalities in calcium and phosphorus worsen. Over time the negative effects of sustained hyperparathyroidism on bone are realized as calcium resorption from bone persists.

FIGURE 63-2

Pathophysiology of CKD-MBD. (Ca, calcium; FGF-23, fibroblast growth factor-23; PTH, parathyroid hormone.) [a]FGF-23 also increases in response to 1,25-dihydroxyvitamin D_3. [b]These adaptations are lost as kidney disease progresses.



Progressive kidney disease
Impaired phosphate excretion
Decreased production of 1,25-dihydroxyvitamin D3
Increased Ca × P product
Phosphate retention
Increased FGF-23
Calcifications
Hypocalcemia
Increased PTH production and secondary hyperparathyroidism
Decreased intestinal calcium and phosphorus absorption
Impaired bone mineralization
Hypocalcemia
Increased calcium mobilization from bone
Increased renal calcium reabsorption
Decreased renal tubular reabsorption of phosphate
Osteitis fibrosa cystica
Renal osteodystrophy
Osteomalacia
Metabolic acidosis
Aluminum overload

1,25-Dihydroxyvitamin D_3 or calcitriol promotes increased intestinal absorption of calcium and phosphorus, which helps normalize ionized calcium. Calcitriol also works directly on the parathyroid gland to suppress PTH production. The enzyme 1-α-hydroxylase is responsible for the final hydroxylation and conversion of the vitamin D precursor, 25-hydroxyvitamin D or 25(OH)D, to calcitriol in the kidney (Fig. 63-3). As kidney disease progresses, the concentrations of calcitriol decline due to loss of 1-α-hydroxylase activity. The resultant vitamin D deficiency leads to reduced intestinal calcium and phosphorus absorption and worsening hyperparathyroidism. Increases in FGF-23 also promote calcitriol deficiency.[16] Calcitriol deficiency is more prevalent in individuals with CKD G4-G5. Deficiency in 25(OH)D (levels of <30 ng/mL [75 nmol/L]) is also common in individuals with CKD due to decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D.

FIGURE 63-3

Vitamin D metabolism. Production of active vitamin D requires conversion of 7-dehydrocholesterol to cholecalciferol (vitamin D_3) by sunlight, followed by the first hydroxylation step in the liver to form 25-hydroxyvitamin D_3 or $25(OH)D_3$, and the final conversion step in the kidney to form 1,25-dihydroxyvitamin D_3 or calcitriol. Within the kidney vitamin D may also be converted to an inactive form $24,25(OH)D_3$. *Vitamin D therapies include calcitriol which is the active compound $1,25(OH)_2D_3$ made endogenously, nutritional vitamin D (NVD) as ergocalciferol (a D_2 compound) or cholecalciferol (a D_3 compound), calcifediol which is $25(OH)D_3$, and the vitamin analogs paricalcitol and doxercalciferol. If NVD is administered, the compound requires conversion to the active form as either a $1,25(OH)D_2$ (as with ergocalciferol) or a $1,25(OH)D_3$ (as with cholecalciferol). Calcitriol and paricalcitol are active as given. Doxercalciferol requires conversion to the active form $[1,25(OH)_2D_2]$ by the liver. Agents in red are vitamin D agents. (DBP, vitamin D binding protein; NVD, nutritional vitamin D; VDRs, vitamin D receptors.)

The abnormalities of CKD-MBD lead to alterations in structural integrity of bone and other associated consequences. The continuous high rate of production of PTH by the parathyroid glands promotes parathyroid hyperplasia. Nodular tissue demonstrates more rapid growth potential and is associated with fewer vitamin D and calcium-sensing receptors, resulting in resistance to exogenous calcitriol therapy. Bone abnormalities are almost universal in dialysis patients and observed in the majority of those with CKD G3-G5.[17] The bone abnormalities include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), and adynamic bone disease. Osteitis fibrosa cystica is most common and is characterized by areas of peritrabecular fibrosis. Bone marrow fibrosis and decreased erythropoiesis are also consequences of severe osteitis fibrosa cystica. Osteomalacia was historically noted in HD patients with aluminum toxicity, a finding less common today due to the decreased use of aluminum-containing phosphate binders and changes in the processing of dialysate solutions to decrease aluminum content. Adynamic lesions are characterized by low amounts of fibrosis or osteoid tissue and low bone formation rates. Multiple risk factors for the development of this bone disease include high concentrations of dialysate calcium along with high doses of calcium-containing phosphate binders, aggressive management with vitamin D therapy, diabetes, and aluminum toxicity.[16]

The morbidity and mortality of CKD patients are increased in individuals with both severe hypo- and hyperparathyroidism.[17] Elevations of serum phosphorus, even within the upper limits of the normal range, have been associated with increased risk of CV events and/or mortality (all-cause or CV mortality) in patients with CKD G3-G5.[18] FGF-23 has also been associated with increased mortality and CV events in individuals with CKD. The incidence of calciphylaxis, or rapid calcification of subcutaneous tissue, in patients with advanced kidney disease has increased over the past decade and has been associated with CKD-MBD, an elevated calcium times phosphorus product, and warfarin use.[17,19] Warfarin inhibits the matrix Gla protein, which is a vitamin-K-dependent protein that prevents calcium deposition in arteries, and may therefore promote vascular calcification in individuals at risk.[20] The decision to initiate warfarin therapy in patients with advanced kidney disease with a clinical indication (eg, atrial fibrillation) should take into account this additional risk of calcifications. Intake of calcium from calcium-based binders may also contribute to coronary artery calcification. These data underscore the need to consider all the consequences of elevated PTH, calcium, and phosphorus, not just their effects on bone.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Anemia and CKD-MBD

Signs and Symptoms

- Anemia: Fatigue, weakness, dizziness, headache, shortness of breath, mental confusion, cold intolerance, cold hands and feet, tingling in the extremities, chest pain, pale skin, irregular heartbeat.
- CKD-MBD: *Clinical presentation varies depending on the prevailing metabolic abnormality and characteristic bone disease (see chapter 69, Calcium and Phosphorus Homeostasis).

Laboratory Tests

- Anemia: Decreased Hb/hematocrit (Hct), transferrin saturation (TSat), and/or ferritin (iron deficiency; note: ferritin may be increased due to inflammatory conditions), may be hemoccult-positive if GI bleeding present. Increased hepcidin.
- CKD-MBD: Decreased vitamin D levels, albumin, and calcium (in early stages of CKD). Increased: phosphorus, PTH, FGF-23, and calcium (more likely in CKD G5 and ESKD).

Diagnostic Considerations for Anemia of Chronic Kidney Disease

Since individuals with anemia of CKD may be asymptomatic, laboratory evaluation is commonly the initial approach to diagnosing anemia of CKD. According to the KDIGO guidelines, Hb concentrations should be measured annually in CKD 3, biannually in CKD 4-5, and at least every 3 months in CKD 5D patients.[14] The diagnosis of anemia is made and further workup of anemia is required when the Hb is less than 13 g/dL (130 g/L; 8.07 mmol/L) for adult males and less than 12 g/dL (120 g/L; 7.45 mmol/L) for adult females. As iron deficiency is the primary cause of resistance to treatment of anemia with ESAs, assessment of the iron status is necessary. The TSat provides information on iron immediately available for use in the bone marrow for red blood cell production and the serum ferritin is in indirect measure of storage iron. The TSat is calculated as follows: (serum iron/total iron-binding capacity [TIBC]) × 100. Transferrin is the carrier protein for iron and may be affected by nutritional status. Serum ferritin is an indirect measure of storage iron and an acute-phase reactant, meaning it may be elevated under certain inflammatory conditions and give a false indication of storage iron. Patients may be diagnosed with *absolute iron deficiency* when both circulating iron and stored iron are low (low TSat and ferritin). In CKD patients absolute iron deficiency has been defined as a TSat < 20% (0.20) and a ferritin of < 100 ng/mL (μg/L; 225 pmol/L) in ND-CKD patients and < 200 ng/mL (μg/L; 449 pmol/L) in HD patients.[7] The term *functional iron deficiency* describes a situation when the TSat is low, but the serum ferritin is not considered low (TSat < 20% [0.20], ferritin > 100 and 200 ng/mL [μg/L; 225 and 449 pmol/L] for ND-CKD and HD patients, respectively). In this situation, iron is not released rapidly enough to satisfy the demands for erythropoiesis and further evaluation is warranted. While there is some controversy regarding the reliability of these definitions, particularly for functional iron deficiency, they do provide a working definition used in clinical practice. The KDIGO guideline for anemia does suggest TSat and serum ferritin thresholds that warrant iron supplementation (Table 63-2).[14]

TABLE 63-2

KDIGO Recommendations for Initiation of Erythropoiesis Stimulating Agents and Iron in Adults with Anemia of Chronic Kidney Disease

	ND-CKD	ESKD
ESA initiation	If Hb <10 g/dL (100 g/L; 6.21 mmol/L). Consider rate of fall of Hb, prior response to iron, risk of needing a transfusion, risk of ESA therapy, and presence of anemia symptoms before initiating an ESA. [2C] Do not initiate if Hb ≥10 g/dL (100 g/L; 6.21 mmol/L). [2D]	Use ESAs to avoid drop in Hb to <9 g/dL (90 g/L; 5.59 mmol/L) by starting an ESA when Hb is between 9 and 10 g/dL (90 and 100 g/L; 5.59 and 6.21 mmol/L). [2B]
Hb level	Do not use ESAs to *intentionally* increase Hb above 13 g/dL (130 g/L, 8.07 mmol/L). [1A] Do not use ESAs to maintain Hb above 11.5 g/dL (115 g/L; 7.14 mmol/L). [2C]	Do not use ESAs to *intentionally* increase Hb above 13 g/dL (130 g/L, 8.07 mmol/L). [1A] Do not use ESAs to maintain Hb above 11.5 g/dL (115 g/L; 7.14 mmol/L). [2C]
Iron initiation[a]	If TSat is ≤30% (0.30) and ferritin is ≤500 ng/mL (µg/L; 1,120 pmol/L). [2C]	If TSat is ≤30% (0.30) and ferritin is ≤500 ng/mL (µg/L; 1,120 pmol/L). [2C]

CKD, chronic kidney disease; ESA, erythropoiesis stimulating agent; ESKD, end-stage kidney disease; Hb, hemoglobin; ND-CKD, non-dialysis CKD patients; QOL, quality of life; TSat, transferrin saturation.

See Chapter 62 for definitions of evidence grading in brackets.

[a] If TSat and serum ferritin are below suggested levels, consider iron supplementation if goal is to increase Hb and/or decrease ESA dose. *Note*: Serum ferritin is an acute-phase reactant-use clinical judgment when above 500 ng/mL (µg/L; 1120 pmol/L).

Data from Reference 14.

Additional workup should be done to evaluate other causes of anemia such as blood loss, deficiencies in vitamin B_{12} or folate, or other disease states that contribute to anemia, including human immunodeficiency virus infection and malignancies (see Chapter 122). Red blood cell indices (mean corpuscular volume, mean corpuscular Hb concentration), white blood cell count, differential and platelet count, and absolute reticulocyte count should also be assessed. A stool guaiac test should be performed to rule out GI bleeding. Measurement of serum erythropoietin concentrations is not generally useful since levels may fall into what is considered a “normal” range but are insufficient relative to the degree of decline in Hb.

Diagnostic Considerations for Chronic Kidney Disease–Related Mineral and Bone Disorder

Symptoms of CKD-MBD are often not evident until significant skeletal damage has developed; consequently, prevention is the key to minimize the risk of long-term complications. When signs and symptoms such as bone pain and skeletal fractures are evident, the disease is not easily amenable to treatment. Thus, the identification of biochemical or imaging abnormalities which typically precede clinical manifestations is an essential component of patient evaluation. The biochemical abnormalities of CKD-MBD that are commonly present in patients with CKD include alterations in serum phosphorus, calcium, PTH, 25(OH)D, and 1,25(OH)$_2$D$_3$ or calcitriol. Because of deficiency in the vitamin D precursor, 25(OH)D is common and has been associated with negative outcomes in the CKD population, measurement of 25(OH)D levels in patients with CKD 3-5D is suggested.[17] The assay methods for 25(OH)D are not standardized, which creates a challenge regarding the clinical implications of abnormal values and limits its value as an indicator of therapeutic response.[21] Current monitoring recommendations and goals of therapy are covered in the “Treatment of CKD-MBD” section.

In addition to evaluating biochemical indices that define CKD-MBD, evaluation of bone architecture may be desirable. The gold standard test for diagnosing bone manifestations of CKD-MBD is a bone biopsy for histologic analysis; however, this is an invasive test that is not easily performed. KDIGO guidelines recommend bone biopsy only in patients in whom the etiology of clinical symptoms and biochemical abnormalities is not clear and the results may lead to changes in therapy.[17] This includes patients experiencing unexplained fractures, persistent hypercalcemia, osteomalacia, an atypical response to standard therapies for elevated PTH, or progressive decreases in bone mineral density despite therapy. Bone biopsy findings are described on the basis of turnover rate, mineralization, and volume. Bone mineral density testing is recommended in patients with CKD G3-G5 and ESKD with evidence of CKD-MBD and/or risk factors for osteoporosis.[17] CKD-MBD is also highly associated with vascular and soft-tissue calcifications, known risk factors for mortality; therefore, diagnostic testing for calcifications should be considered in the evaluation for CKD-MBD.

TREATMENT OF SECONDARY COMPLICATIONS

General Approach to Treatment of CKD Complications

④ Management of complications of CKD should be based on the KDIGO consensus guidelines which are based on evidence, when available, and expert recommendations. There are guidelines provided by the Kidney Disease Outcome Quality Initiative (KDOQI) for many of the associated complications; however, this chapter emphasizes KDIGO guidelines, which are international guidelines and, in most cases, based on data or opinion. Chapter 62 includes a guide to the grading and strength of recommendations used in these guidelines.

⑤ An interdisciplinary approach to care should emphasize patient-centered care and at minimum include a team of nephrologists, nurses, dietitians, pharmacists, and social workers. This team approach puts the patient at the center and includes individuals trained to address many of the complex secondary complications of CKD and provide patient education about CKD, the associated complications, and their management. Treatment of secondary complications of CKD requires a number of pharmacologic intervention, thus, adding to the number of medications required for patients with advanced CKD. Pharmacists are readily accessible medication experts equip to address medication-related problems and provide comprehensive medication management.

Anemia

Desired Outcome

The desired outcomes of anemia management are to safely achieve target Hb levels that increase oxygen-carrying capacity to decrease signs and symptoms of anemia and reduce the need for blood transfusions. Hb is the preferred monitoring parameter for red blood cell production because, unlike Hct, its concentration is not affected by blood storage conditions and instrumentation used for analysis. Initiation of iron or ESA therapy is guided by the patient's Hb, TSat, and ferritin (Table 63-2).[14] The risk of mortality and CV events is higher in CKD patients treated to higher Hb target values with an ESA. There are discrepancies, however, in the FDA-approved labeling for ESAs and the KDIGO anemia guidelines in terms of target Hb, with more conservative Hb of 10 to 11 g/dL (100-110 g/L; 621-683 mmol/L) recommended by the FDA for individuals with ESKD.[14]

Despite associations of development of left ventricular hypertrophy (LVH) with worsening anemia, there are no prospective studies demonstrating that early and aggressive treatment improves CV end points or reduces LVH in CKD patients. Improvements in the quality of life are not universally observed with increases in Hb and such perceived improvements must be weighed against reported risks associated with using ESAs to achieve near-normal Hb levels in the CKD population.[22]

Target Hemoglobin and Use of Erythropoiesis Stimulating Agents

The target range for Hb in the CKD population has been a topic of much debate. Although the benefits of achieving a normal or near normal Hb seemed rational when ESAs became available in the late 1980s, the Normal Hematocrit Cardiac Trial (NHCT),[23,24] the Correction of Hb and Outcomes in Renal Insufficiency (CHOIR),[25] and the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin-Beta (CREATE)[26] trials later proved otherwise, and the suggested target Hb at the time of those trials of 11 to 12 g/dL (110-120 g/L; 6.83-7.45 mmol/L) was subsequently lowered. Several FDA advisories have been released and changes were made to the precautions, black box warning, and dosing sections of ESA product labeling promoting more conservative use of ESAs.[27] The current labeling for all ESAs warns that dosing ESAs to target Hb levels greater than 11 g/dL (110 g/L; 6.83 mmol/L) for CKD patients increases the risk for death, serious CV reactions, and stroke. Practitioners are advised to consider ESAs in patients with CKD only when the Hb is below 10 g/dL (100 g/L; 6.21 mmol/L) and to individualize therapy to use the lowest ESA dose necessary to decrease the need for red blood cell transfusions.

Of concern is the fact that CHOIR demonstrated that targeting Hb levels above 11 g/dL (110 g/L; 6.83 mmol/L) with ESA therapy in individuals with CKD not requiring dialysis resulted in increased risk of mortality and CV events compared with patients maintained in a lower Hb range (trial was terminated early).[25] CREATE demonstrated no benefit of targeting a higher Hb target (13-15 g/dL [130-150 g/L; 8.07-9.31 mmol/L]) to reduce CV events in the non-dialysis CKD patients.[26] An increased risk of all-cause mortality with ESA treatment was also reported in a meta-analysis of nine randomized controlled trials that included over 5,100 CKD patients treated to Hb targets in the range of 12 to 16 g/dL (120-160 g/L; 7.45-9.93 mmol/L).[28] There was also a higher risk of dialysis access thrombosis and uncontrolled blood pressure in the higher Hb groups. Results from the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) also failed to support a higher Hb.[29] In addition, there was also an almost twofold increase in the risk of stroke (5% in the treatment group vs 2.6% in the placebo group), a finding that was not associated with baseline characteristics of the patients or other potential risk factors. Those patients with a history of cancer in the higher Hb group also had a higher risk of death.

The overall negative CV outcomes observed with higher Hb targets in the randomized trials have prompted much discussion about the potential causes, including not only ESA dose and Hb target, but also the rate of rise in Hb and the variability in Hb over time (eg, degree of fluctuation in Hb). Individuals in the CHOIR study who were able to achieve the target Hb did not have worse outcomes. Further analysis of the NHCT data also showed a reduction in mortality by 60% for those individuals who responded to epoetin therapy compared with nonresponders.[24] Resistance to ESAs was associated with higher one-year mortality and hospitalization for CV events.[30] Such findings have led to discussion of whether hyporesponsiveness to ESAs due to other conditions such as inflammation may explain the higher event rates in this group of individuals.

Nonpharmacologic Therapy

Nonpharmacologic therapy for anemia of CKD includes maintaining adequate dietary intake of iron as well as folate and B_{12}. A relatively small amount of dietary iron, approximately 1 to 2 mg, is absorbed each day, primarily in the duodenum. While oral intake or iron should be encouraged, iron from dietary sources alone is insufficient to meet the increased iron requirements from initiation of ESA therapy.

Pharmacologic Therapy

⑥Pharmacologic therapy for anemia of CKD includes iron supplementation to prevent and correct iron deficiency and ESAs to correct erythropoietin deficiency. Iron supplementation is first-line therapy for anemia of CKD if iron deficiency is present, and for some patients, the target Hb may be achieved with iron therapy alone. For most individuals with advanced CKD, however, combined therapy with iron and an ESA will be necessary to achieve the target Hb.

Now, two HIF prolyl hydroxylase inhibitors (HIF-PHIs) (roxadustat and vadadustat) are under consideration for approval by the Food and Drug Administration. These HIF-PHIs are orally administered medications that have been studied in patients with ND-CKD and ESKD with positive results in terms of improving Hb and decreasing hepcidin levels to promote better iron distribution and utilization, without raising erythropoietin levels to levels achieved with exogenous ESA administration.[31] Agents within this drug class have been approved outside the United States and are part of the pharmacologic regimen for the management of anemia of CKD.

Iron Supplementation

Iron formulations are available for administration orally, intravenously, or through the dialysate used for hemodialysis. Iron supplements provide the elemental iron required for production of Hb and its subsequent incorporation in red blood cells, the net result of which is an increase in the transportation of oxygen to tissues. Iron supplementation is necessary to treat *absolute iron deficiency*, but may also be warranted in individuals with a TSat less than 30% (0.30) and a ferritin less than 500 ng/mL (μg/L; 1120 pmol/L) in whom an increase in Hb or a decrease in ESA dose is desired (KDIGO suggestion).[14] Patients with *functional iron deficiency* may also benefit from iron supplementation. The optimal upper limit for these iron indices is not clearly defined and clinicians must balance achieving adequate iron for erythropoiesis with safety in terms of preventing adverse consequences such as iron overload and concerns with nontransferrin (unbound) iron.

The preferred route of administration depends on CKD stage, severity of iron deficiency, tolerability of and prior response to oral iron, history of adverse reactions to IV iron, availability of IV access, and cost (see the "Therapeutic Options" section). KDIGO recommends either oral or IV iron administration in non-HD patients (eg, CKD stage G3 or higher and PD patients) and IV supplementation for patients with ESKD.[14] The National Institute for Health Care Excellence (NICE) guidelines suggest a trial of oral iron (for up to 3 months) in ND-CKD patients not receiving an ESA and IV iron for patients treated with and ESA and/or on HD.[32] Oral iron supplementation is more convenient for ND-CKD patients since they do not have regular IV access; however, at some point they are likely to require IV iron supplementation to correct absolute iron deficiency, especially if they are receiving an ESA. If oral therapy is initiated, a 1- to 3-month trial is recommended to assess response. In patients with CKD on hemodialysis, GI absorption of iron is often inadequate to meet the increase in iron demand from ESA therapy and chronic blood loss, due largely to the effects of hepcidin on GI absorption. Thus, the IV route is preferred for almost all HD patients.[14] IV administration is also recommended in the PD population, although the desire to preserve potential future venous access sites for HD (if needed) must be considered. Parenteral iron improves the responsiveness to ESA therapy and, thus, lower ESA doses can be used to maintain the target Hb in HD patients.[14] In the FIND-CKD trial, 624 ND CKD patients were randomized to IV ferric carboxymaltose administered at high dose (1,000 mg every 4 weeks) to target a ferritin of 400 to 600 ng/mL (µg/L; 899-1348 pmol/L), low dose (200 mg every 4 weeks) to target a ferritin of 100 to 200 ng/mL (µg/L; 225-449 pmol/L), or oral iron administered as 200 mg/day. After 56 weeks, the high ferritin IV iron group had better outcomes in terms of the increase in mean Hb at 12 months and time to achieve that level, but no differences in adverse events. Iron administration in patients with functional iron deficiency (ie, low TSat, high serum ferritin) should be decided on an individual basis. A trial of IV iron therapy may be warranted if the Hb is less than desired despite high-dose ESA therapy as long as potential risks of IV therapy are considered (see the “Adverse Effects” section).

Therapeutic Options

Multiple oral and IV products are marketed in the United States. Oral iron preparations include ferrous and ferric salts (ferrous sulfate, ferrous fumarate, ferrous gluconate, ferric citrate, and ferric maltol), polysaccharide iron complex, and carbonyl iron. These forms of iron differ in terms of the amount of elemental iron (Table 63-3). A heme iron polypeptide formulation is also available and contains 12 mg of elemental iron. Numerous nonprescription products that contain ferrous salts and iron polysaccharide are available. Ferric maltol is a newer agent available by prescription containing 100% elemental iron that is approved for iron deficiency anemia in adults. Ferric citrate was originally developed as a phosphate binding agent but was subsequently shown to improve iron status and Hb levels also, leading to its approval for treatment of iron-deficiency anemia in ND-CKD patients.[33]

TABLE 63-3

Oral Iron Agents

Preparation	Brand Names[a]	% Elemental Iron	Commonly Rx'd
			Unit Size in mg (Amount elemental iron)
Carbonyl iron	Feosol, Ferralet (combo with ferrous gluconate, docusate)	100	45 (45)
Ferric citrate[b]	Auryxia	21	1000 (210)
Ferric maltol[b]	Accufer	100	30 (30)
Ferrous fumarate	Femiron, Feostat	33	200 (66)
Ferrous gluconate	Simron, Fergon	12	325 (38)
Ferrous sulfate	Feosol, Fer-In-Sol	20	325 (65)
Iron Polysaccharide	Niferex, Nu-Iron	100	150 (150)

[a] Not all inclusive for over-the-counter medications (ie, ferrous salts).

[b] Available by prescription only.

Iron is absorbed from the GI tract via the divalent metal transporter 1 in the duodenum and upper jejunum where approximately 10% of orally administered iron is absorbed. Ferroportin transports iron across the mucosal cell to the blood where it is bound to transferrin. Immediate release oral iron agents are preferred over enteric coated and slow or sustained release products, which are absorbed more distally in the GI tract and not as readily absorbed. Absorption of iron is decreased by food and achlorhydria. Some oral iron formulations also include ascorbic acid to enhance iron absorption, although data to support this practice are lacking. The role of hepcidin to decrease GI absorption is also a significant factor that influences iron regulation and a reason that oral therapy may be inadequate to meet iron needs, particularly in HD patients.

Soluble ferric pyrophosphate citrate (Triferic) is an iron compound approved for iron replacement in patients with ESKD on HD and may be administered via the dialysate during HD or intravenously using the IV formulation (Triferic AVNU). When administered in the dialysate, this agent crosses to the blood side of the dialyzer by diffusion to allow for continuous iron administration during the procedure. Ferric pyrophosphate citrate is a mixed-ligand iron complex with iron bound to pyrophosphate and citrate. Once in the systemic circulation ferric pyrophosphate binds directly to transferrin, bypassing the reticuloendothelial system, and is delivered to the bone marrow for use in red blood cell production. Studies to date have shown an increase in Hb concentration and a reduction in ESA dose and IV iron requirements, but no significant increase in ferritin or in nontransferrin bound iron.[34,35] These findings are important when considering the potential adverse effects associated with iron accumulation and free (unbound) iron.

Most IV iron preparations are colloids that consist of an iron-containing core that is surrounded by a carbohydrate shell to stabilize the iron complex. Available agents differ in the size of the core and the composition of the surrounding carbohydrate. Such differences affect the rate of dissociation of iron from the complex, the rate of distribution, and the maximum tolerated dose and rate of infusion. The IV iron products that are currently available in the United States are shown in Table 63-4.

TABLE 63-4

Intravenous Iron Agents

Iron Compounds	Brand Names	Molecular Weight (Daltons)	FDA-Approved Indications	FDA-Approved Dosing[a]
Ferric carboxymaltose	Injectafer	150,000	Adult patients with intolerance to oral iron or who have had an unsatisfactory response to oral iron and in adult patients with CKD not on dialysis	Give 2 doses separated by at least 7 days of 750 mg per dose (if body weight is ≥50 kg) or 15 mg/kg per dose (if body weight is <50 kg) not to exceed 1,500 mg per course. Give either IV push (100 mg/min) or diluted in not more than 250 mL of 0.9 NaCl as an infusion over at least 15 minutes
Ferric derisomaltose	Monoferric	155,000	Treatment of iron deficiency anemia in adults with ND-CKD or who have intolerance to oral iron or unsatisfactory response to oral iron	If weight ≥ 50 kg: 1,000 mg as a single dose If weight < 50 kg administer 20 mg/kg actual body weight as a single dose
Ferric pyrophosphate citrate	Triferic AVNU	1,313	Iron replacement to maintain Hb in adult patients with ESKD on hemodialysis	6.75 mg iron over 3 to 4 hours at each HD session via pre-dialyzer infusion line, post-dialyzer infusion line, or a separate connection to the venous blood line
	Triferic			Add the appropriate ampule or powder packet* to the bicarbonate concentrate solution to achieve a final concentration of ferric pyrophosphate citrate of 110 μg/L (*add one 5 mL ampule to 2.5 gallons (9.5 L)of bicarbonate concentrate or one 50 mL ampule to 25 gallons (95 L) of bicarbonate or one packet of powder to each 25 gallons ampule (95 L)
Ferumoxytol	Feraheme	750,000	Adult patients with iron-deficiency anemia associated with chronic kidney disease	510 mg (17 mL) as a single dose, followed by a second 510 mg dose 3-8 days after the initial dose. Dilute in 50-200 mL of 0.9% NaCl or 5% dextrose and administer as an IV infusion over 15 minutes
Iron dextran	INFeD	96,000	Patients with iron deficiency in whom oral iron is unsatisfactory or impossible	100 mg over 2 minutes (25-mg test dose required) Note: Equation provided by manufacturer to calculate dose based on desired Hb
Iron sucrose	Venofer	43,000	Adult and pediatric ESKD patients on HD age 2 years and older	Adult: 100 mg over 2-5 minutes or 100 mg in maximum of 100 mL of 0.9% NaCl over 15 minutes per consecutive HD session Pediatric: 0.5 mg/kg not to exceed 100 mg per dose over 5 minutes or diluted in 25 mL of 0.9% NaCl administered over 5-60 minutes (give dose every 2 weeks for 12 weeks)
			Adult and pediatric ND-CKD patients age 2 years and older	Adult: 200 mg over 2-5 minutes on five different occasions within 14-day period. There is limited experience with administration of 500 mg diluted in a maximum of 250 mL of

				0.9% NaCl over 3.5-4 hours on days 1 and 14 Pediatric: see pediatric dosing for CKD 5HD (give dose every 4 weeks for 12 weeks)
			Adult and pediatric ESKD patients on PD, age 2 years and older	Adult: Give 3 divided doses within 28 days as 2 infusions of 300 mg over 1.5 hours 14 days apart followed by one 400 mg infusion over 2.5 hours 14 days later. Dilute in a maximum of 250 mL of 0.9% NaCl Pediatric: see pediatric dosing for CKD 5HD (give dose every 4 weeks for 12 weeks)
Sodium ferric gluconate	Ferrlecit	350,000	Adult and pediatric ESKD patients on HD age 6 years and older receiving ESA therapy	Adult: 125 mg over 10 minutes or 125 mg in 100 mL of 0.9% NaCl over 60 minutes Pediatric: 1.5 mg/kg in 25 mL of 0.9% NaCl over 60 minutes; maximum dose 125 mg per dose

CKD, chronic kidney disease; ESA, erythropoiesis stimulating agent; ESKD, end-stage kidney disease; HD, hemodialysis; ND-CKD, non-dialysis CKD patients.

[a] Monitor for 30 minutes following an infusion; KDIGO guidelines recommend monitoring for 60 minutes (1B recommendation for iron dextran, 2C recommendation for non-dextran products).

[b] With the exception of ferric carboxymaltose, ferric derisomaltose, and ferumoxytol, small doses (eg, 25-150 mg/wk) are generally used for maintenance regimens. Larger doses (eg, 1 g) should be administered in divided doses.

Adverse Effects

Adverse effects of oral iron are primarily GI in nature and include constipation, nausea, and abdominal cramping (see Chapter 122). These adverse effects are more likely as the dose is escalated. These unfavorable effects often discourage patients from taking these medications on a chronic basis. Some of these GI side effects can be minimized if oral iron products are taken with food; however, food may decrease absorption of oral iron.

Adverse effects of IV iron include allergic reactions, hypotension, dizziness, dyspnea, headaches, lower back pain, arthralgia, syncope, and arthritis. Some of these reactions, in particular hypotension, can be minimized by decreasing the dose or rate of infusion of iron. The most concerning potential consequence of IV iron administration is anaphylaxis. Serious reactions to iron dextran including respiratory complications and CV collapse have been reported in approximately 0.6% to 0.7% of patients.[14] Such reactions are believed to be partly a response to antibody formation to the dextran component. Adverse reactions were reported more frequently with the brand product Dexferrum (no longer available) compared with INFeD.[14] Iron dextran carries a black box warning of the risk of anaphylactic-type reactions, including fatalities, and a 25-mg test dose is required. An analysis of anaphylaxis risk in patients newly exposed to IV iron products (including dextran, gluconate, sucrose, or ferumoxytol) reported the highest risk for iron dextran with the lowest risk with iron sucrose.[36]

The non-dextran IV iron formulations have a better safety record than either of the iron dextran products. The labeling for these formulations also includes a warning of the risk of hypersensitivity reactions. Following the approval of ferumoxytol in 2009, there were 79 cases of anaphylactic reactions, of which 18 were fatal.[37] Almost half of the cases occurred with the first dose and approximately 75% occurred during the infusion or within 5 minutes of completion. In 2015, the FDA required a black box warning for ferumoxytol noting that fatal and serious hypersensitivity reactions including anaphylaxis have occurred and that the risks and benefits should be considered in patients with a history of multiple drug allergies. Ferumoxytol should not be administered IV push, but should be diluted and administered as an IV infusion (see Table 63-4). As a superparamagnetic oxide, ferumoxytol may alter the diagnostic ability of magnetic resonance imaging studies for up to 3 months after administration; therefore, they should be done prior to administration of ferumoxytol whenever possible.

Long-term administration of IV iron also introduces a risk of iron overload. Deposition of excess iron may affect several organ systems, leading to hepatic, pancreatic, and cardiac dysfunction. Bone marrow biopsy provides the most definitive diagnosis of iron overload, but because it is an extremely invasive procedure, it is not widely employed in most clinical settings. Maintaining target serum ferritin and TSat values is the most reasonable approach to minimize the risk of iron toxicity. The challenge is in defining what should be the upper limit, particularly for serum ferritin, which may be elevated in inflammatory conditions and not reflective of true iron stores in such situations. If symptomatic overload does occur, iron chelating agents such as deferoxamine (Desferal), deferiprone (Ferriprox), deferasirox (Exjade), or phlebotomy may be necessary.

More conservative use of ESAs has led to an increase in iron supplementation. This has raised some concerns regarding the potential detrimental effects of increased iron exposure and higher TSat and ferritin targets on patient outcomes (eg, infection, mortality, hospitalizations). Specific concerns relate to the ability of iron to promote infection since iron is essential for infectious microorganisms, increased risk of oxidative stress, and subsequent cardiovascular complications, as well as the concerns of other effects of non-transferrin bound iron (unbound/free iron). Data from clinical trials do not confirm unequivocally that exposure to IV iron in CKD patients treated with ESA therapy increases patient morbidity or mortality.[7,38–42]

A large randomized controlled trial in the United Kingdom (PIVOTAL trial) evaluated the safety of high-dose IV iron (400 mg/month) administered proactively (with the upper TSat limit 40% [0.40] and ferritin of 700 ng/mL [μg/L; 1573 pmol/L]) and low-dose IV iron (0-400 mg monthly) administered reactively (with a TSat < 20% [0.20] or a ferritin < 200 ng/mL [μg/L; 449 pmol/L] prompting the need for IV iron administration) in 2,141 dialysis patients over a median of 2 years.[38] There were significantly fewer deaths and nonfatal CV events (nonfatal MI, stroke, hospitalization for heart failure) in the high-dose group compared to the low-dose group and a lower requirement for ESAs and transfusions. The high-dose and low-dose IV iron groups exhibited identical infection rates.[42] This is the most robust evidence to date that IV iron at this dose level and prespecified iron targets is safe in HD patients. Caution is recommended with the use of IV iron doses higher than those used in the PIVOTAL trial as observational data have suggested associations with increased risk of mortality and infection. Although more data are needed to draw conclusions, the general consensus is that administration of IV iron in the setting of an active infection is not recommended.[7] The benefits of correcting iron deficiency in patients with CKD should also be considered in the clinical decision process.

Drug Interactions

Drug interactions with oral iron are common. Iron absorption is decreased by other elements (eg, calcium in calcium-containing phosphate binders), medications that increase the pH of the GI tract such as proton pump inhibitors and H_2-antagonists, and antibiotics including doxycycline and tetracycline. Iron also decreases absorption of other drugs such as antibiotics (fluoroquinolones, doxycycline).

If oral therapy is initiated, the suggested dose is 200 mg of elemental iron per day for most available agents. The approved dose of ferric maltol is 30 mg twice daily. The recommended dose of ferric citrate in ND CKD patients is 210 mg three times daily. With numerous oral agents to choose from, the best option is one that provides adequate elemental iron with the fewest number of dosage units required per day and the lowest incidence of adverse effects. Strategies to improve absorption and potentially minimize adverse GI events have been evaluated in non-CKD patients and include single-dose administration of ferrous sulfate on alternate days, which resulted in a decrease in hepcidin and improved iron absorption, although such data in CKD patients are not available.[43] KDIGO guidelines suggest a 1- to 3-month trial of oral therapy in the non-HD CKD population prior to initiating IV therapy.[14]

For the HD population, IV therapy is preferred with administration of a 1-g course of IV iron (in divided doses) historically used to replete patients with an absolute iron deficiency. The amount per dose and rate at which to administer IV iron depends on the product (see Table 63-4). Typical repletion dosing regimens for IV iron are 100 mg as iron sucrose over 10 dialysis sessions or 125 mg of sodium ferric gluconate over eight dialysis sessions to provide a total of 1 g. As a general practice, if IV iron doses higher than those currently approved are needed, they should be infused over a longer period of time (eg, at least 2-4 hours) due to the risk of hypersensitivity reactions, hypotension, dizziness, and nausea. The newer agents, ferumoxytol, ferric carboxymaltose, and ferric derisomaltose differ in terms of how rapidly iron is released from the compound, which allows for higher single doses to be administered compared to the other IV iron agents (Table 63-4). Ferric pyrophosphate citrate when given IV is approved at smaller doses of 6.75 mg given over 2 to 4 hours during each HD session. When administered via the dialysate used for HD, the ampule or powder is added to the bicarbonate concentrate solution used for dialysis to achieve a final concentration of 110 μg/L.

Without ongoing iron supplementation, many patients quickly become iron deficient. To prevent iron deficiency and the need for intermittent repletion doses, maintenance doses of IV iron should be administered in HD patients (eg, iron sucrose 25-100 mg/wk; sodium ferric gluconate 62.5-125 mg/wk).[14] There are many different maintenance dosing protocols in clinical practice for CKD patients and some controversy as to the maximum monthly doses given safety concerns (see the “Adverse Events” section). The main consideration is to provide enough iron to help achieve goal hemoglobin levels and to reduce the need for ESAs and transfusions, while minimizing risks of IV iron.

Administration of a 25-mg test dose is required for all iron dextran products. This test dose should be administered over at least 30 seconds. It is recommended that patients be observed for at least 1 hour before administering the remainder of the dose. For this reason, the non-dextran agents are predominantly used in the CKD population. Regardless of which IV iron agent is used, all patients should be monitored for signs and symptoms of hypersensitivity for at least 30 minutes following completion of a dose. KDIGO clinical practice guidelines suggest monitoring patients for at least 60 minutes following administration of IV iron; a 1B recommendation for iron dextran products and a 2C recommendation for non-dextran formulations.[14] These agents should only be administered when personnel and therapies are immediately available for the treatment of anaphylaxis and other hypersensitivity reactions.

Erythropoiesis-Stimulating Agent Therapy

Since FDA approval of epoetin-alfa in 1989, ESA therapy has become an integral part of the care for patients with CKD. ESAs available in the United States are listed in Table 63-5. The biosimilar epoetin-alfa epbx is approved in the United States. As a biosimilar, this agent has the same indications as the biological drug, epoetin-alfa.

TABLE 63-5

Erythropoiesis-Stimulating Agents in Chronic Kidney Disease

Drug Name	Brand Name(s)	Starting Dose	Route of Administration	Half-Life (Hours)
Epoetin-alfa	Epogen, Procrit	Adults: 50-100 units/kg three times per week Pediatrics: 50 units/kg three times per week	IV or SubQ	8.5 (IV) 24 (SubQ)
Epoetin-alfa-epbx	Retacrit	See epoetin-alfa information		
Darbepoetin alfa	Aranesp	Adults: ND-CKD: 0.45 μg/kg once every 4 weeks ESKD: 0.45 μg/kg once per week or 0.75 μg/kg every 2 weeks Pediatrics: 0.45 μg/kg once weekly; may give 0.75 μg/kg once every 2 weeks in ND-CKD patients	IV or SubQ	25 (IV) 48 (SubQ)
Methoxy PEG-epoetin-beta	Mircera	All adult CKD patients: 0.6 μg/kg every 2 weeks; Once Hb stabilizes, double the dose and administer monthly (eg, if administering 0.6 μg/kg every 2 weeks, give 1.2 μg/kg every month)	IV or SubQ	134 (IV) 139 (SubQ)

CKD, chronic kidney disease; ESKD, end-stage kidney disease; ND-CKD, non-dialysis CKD patients; PEG, Polyethylene glycol; SubQ, subcutaneous.

Pharmacology and Mechanism of Action

Epoetin-alfa is a glycoprotein manufactured by recombinant DNA technology that has the same amino acid sequence as endogenous erythropoietin. Darbepoetin alfa has two additional *N*-linked carbohydrate chains that decrease the affinity for the erythropoietin receptor, but yield a longer duration of activity compared with erythropoietin. Methoxy PEG-epoetin-beta was created by the addition of an amide bond between the N-terminal or ε-amino group of epoetin-beta and methoxy polyethylene glycol butanoic acid. The compound, which is referred to as a continuous erythropoietin receptor activator (CERA), has a much longer half-life than the other ESAs. All ESAs have the same biologic activity as endogenous erythropoietin in that they bind to and activate the erythropoietin receptor to stimulate erythropoiesis.

Pharmacokinetics and Pharmacodynamics

All available ESAs may be administered via either the IV or the subcutaneous (SC) route. Although bioavailability is less with SC than with IV administration, the prolonged absorption phase leads to an extended half-life (see Table 63-5). Thus, the same target Hb can be achieved and maintained at SC epoetin doses 15% to 30% lower than IV doses.[14] The prolonged half-lives of darbepoetin-alfa and methoxy PEG-epoetin-beta offer the advantage of less-frequent dosing. This is of particular benefit for individuals with CKD who are not yet receiving dialysis and those receiving PD since these patients are not in a clinical setting as frequently as HD patients and do not have regular IV access.

The pharmacodynamic effect of ESAs is important to consider when evaluating response to therapy. With initiation of ESA therapy or a change in dose, the Hb may begin to rise as the result of demargination of reticulocytes; however, it takes approximately 10 days before erythrocyte progenitor cells mature and are released into the circulation. The Hb continues to increase until the life span of the cells stimulated by ESA therapy is reached (mean 2 months; range 1-4 months in patients with ESRD). At this point, a new steady state is achieved (ie, the rate at which red blood cells are being produced equals the rate at which they are leaving the circulation). For this reason, evaluate the Hb response over several weeks and not make dosing changes too soon.

Efficacy

Patients will generally respond to ESA therapy in a dose-related fashion. The most common causes of resistance are iron deficiency, acute illness, inflammation, infection, chronic bleeding, aluminum toxicity, malnutrition, hyperparathyroidism, cancer, and chemotherapy.[14] Deficiencies in folate and vitamin B_{12} should also be considered as potential causes of resistance to ESA therapy, as both are essential for optimal erythropoiesis. Use of ACEIs and ARBs has also been associated with hyporesponsiveness to ESA therapy.[14]

Hypertension is the most common adverse event reported with ESAs and may be associated with the rate of rise in Hb.[10] Hypertensive encephalopathy has also been observed. According to FDA-approved product labeling, ESAs should not be used in those with uncontrolled blood pressure. Protocols established in some clinical settings recommend withholding ESA therapy if blood pressure is above a defined threshold; however, others advocate more judicious use of antihypertensive agents and dialysis to control blood pressure. Seizures have occurred in patients treated with ESAs, particularly within the first 90 days of starting therapy. Thrombosis of the HD vascular access site and other thromboembolic events were reported when ESAs were used to target Hb greater than 13 g/dL (130 g/L; 8.07 mmol/L).[44] The potential for these adverse effects calls for close monitoring of the rate of rise in Hb, changes in blood pressure, and neurologic symptoms following initiation of therapy or a change in ESA dose.

Antibody-associated pure red cell aplasia (PRCA), caused by induction of antibodies directed against the ESA molecule, was reported in the late 1990s and early 2000 and was primarily associated with subcutaneous administration of Eprex, an epoetin-alfa formulation manufactured outside the United States.[45] This reaction was potentially a result of organic compounds being formed when the stabilizing agent polysorbate was used in combination with uncoated rubber stoppers in the prefilled syringes. There have been few cases since changes in the packaging of this product were made; however, the cause of PRCA with this formulation has been disputed.[46] Of note, there have been reports of PRCA with methoxy PEG-epoetin-beta.[47] An evaluation for PRCA should be considered for patients receiving ESA therapy for more than 8 weeks who develop either a rapid decrease in Hb level (rate of 0.5-1 g/dL/wk [5-10 g/L/wk; 0.31-0.62 mmol/L/wk]) or require one to two blood transfusions per week, and have an absolute reticulocyte count of less than 10,000/μL (10×10^9/L) with a normal platelet and white blood cell count.[14] Discontinuation of ESA therapy is recommended if antibody-mediated PRCA develops because antibodies are cross-reactive and continued exposure may lead to anaphylactic reactions (a grade 1A recommendation).

ESAs have also been associated with a reduction in overall survival and increased risk of progression of certain tumor types among CKD patients (eg, head and neck). ESAs are not indicated in patients receiving myelosuppressive chemotherapy when the anticipated outcome is cure. These are important effects to consider when managing a CKD patients with an oncologic disorder.[48]

Drug-Drug Interactions

No significant drug interactions have been reported with the available ESAs.

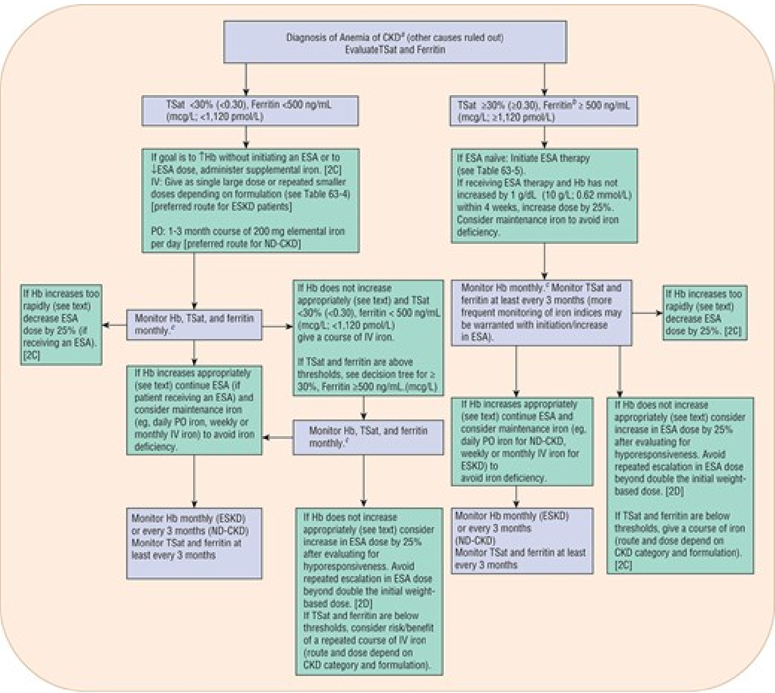
Dosing and Administration

Recommended starting doses of ESA are listed in Table 63-5. Less-frequent dosing of epoetin-alfa (eg, every 1-2 weeks) is effective and may be preferred for ND-CKD patients since these individuals are seen in the outpatient clinical setting on a relatively infrequent basis. Subcutaneous dosing is also more convenient in this population and in PD patients who do not have regular IV access. Conversion tables for patients who are to be switched from epoetin-alfa (units/wk) to darbepoetin-alfa (μg/wk) are available in the labeling information for darbepoetin.[49] There is also a conversion chart for patients being converted from epoetin-alfa or darbepoetin-alfa to methoxy PEG-epoetin-beta.[47]

When starting an ESA, Hb levels should be monitored at least monthly (weekly may be preferred) until stable and then monthly thereafter. Dose adjustments should be made based on Hb response with a goal of avoiding an excessively quick rise or the achievement of values above the recommend target values. An acceptable rate of increase in Hb is 1 to 2 g/dL (10-20 g/L; 0.62-1.24 mmol/L) per month. As a general rule, ESA doses should not be increased more frequently than every 4 weeks, although decreases in dose may occur more frequently in response to a rapid rate of rise in Hb. The dose should be reduced by at least 25% if the Hb increases by more than 1 g/dL (10 g/L; 0.62 mmol/L) in a 2-week period.[10] The dose should be reduced or temporarily discontinued if the Hb level approaches or exceeds 11 g/dL (110 g/L; 6.83 mmol/L) in dialysis patients or 10 g/dL (100 g/L; 6.21 mmol/L) in patients with CKD not requiring dialysis. KDIGO recommendations advocate a decrease in dose as opposed to withholding the ESA when a decrease in Hb concentration is desired (2C grade recommendation).[14] A 25% increase in dose may be considered if the Hb has not increased by 1 g/dL (10 g/L; 0.62 mmol/L) after 4 weeks of ESA treatment and if no causes of hyporesponsiveness to the ESA have been identified. For patients who do not respond adequately over a 12-week escalation period, an increase in ESA dose is unlikely to improve response and may increase risks. Initial hyporesponsiveness to ESAs should be considered when there is no increase in Hb from baseline after the first month of appropriate weight-based dosing. In this situation escalations in ESA dose beyond double the initial weight-based dose should be avoided (a grade 2D recommendation). Acquired ESA hyporesponsiveness may be suspected when patients previously on a stable ESA dose require two increases in ESA doses up to 50% beyond the previously utilized stable dose.[14] In this situation, repeat escalations in ESA dose beyond double the dose at which they had been stable should be avoided (a grade 2D recommendation). The lowest dose of ESA should be used to maintain an Hb level sufficient to reduce the need for red blood cell transfusions. Figure 63-4 provides an approach to management of anemia using ESAs and iron therapy in patients with CKD.

FIGURE 63-4

Algorithm for management of anemia of CKD in adults.[14,44] (CKD, chronic kidney disease; ESKD, end-stage kidney disease; ESA, erythropoiesis-stimulating agent; Hb, hemoglobin; ND-CKD, non-dialysis CKD patients; TSat, transferrin saturation.) Evidence grading in brackets. [a]See Table 63-2 and text for discussion of Hb levels. [b]Clinical judgment should be used to determine if iron supplementation should be continued when ferritin >500 ng/mL (μg/L; 1,120 pmol/L). [c]Weekly monitoring of Hb may be warranted. Wait at least 1 week after an IV dose of iron to measure TSat and ferritin.



Diagnosis of Anemia of CKDa (other causes ruled out)
EvaluateTSat and Ferritin
TSat <30% (<0.30), Ferritin <500 ng/mL (mcg/L; <1,120 pmol/L)
TSat ≥30% (≥0.30), Ferritinb ≥ 500 ng/mL (mcg/L; ≥1,120 pmol/L)
If goal is to ↑Hb without initiating an ESA or to ↓ESA dose, administer supplemental iron. [2C]
IV: Give as single large dose or repeated smaller doses depending on formulation (see Table 63-4) [preferred route for ESKD patients]
PO: 1-3 month course of 200 mg elemental iron per day [preferred route for ND-CKD]
If ESA naive: Initiate ESA therapy (see Table 63-5).
If receiving ESA therapy and Hb has not increased by 1 g/dL (10 g/L; 0.62 mmol/L) within 4 weeks, increase dose by 25%.
Consider maintenance iron to avoid iron deficiency.
If Hb increases too rapidly (see text) decrease ESA dose by 25% (if receiving an ESA). [2C]
Monitor Hb, TSat, and ferritin monthly.c
If Hb does not increase appropriately (see text) and TSat <30% (<0.30), ferritin < 500 ng/mL (mcg/L; <1,120 pmol/L) give a course of IV iron.
If TSat and ferritin are above thresholds, see decision tree for ≥ 30%, Ferritin ≥500 ng/mL (mcg/L)
Monitor Hb monthly.c Monitor TSat and ferritin at least every 3 months (more frequent monitoring of iron indices may be warranted with initiation/increase in ESA).
If Hb increases too rapidly (see text) decrease ESA dose by 25%. [2C]
If Hb increases appropriately (see text) continue ESA (if patient receiving an ESA) and consider maintenance iron (eg, daily PO iron, weekly or monthly IV iron) to avoid iron deficiency.
Monitor Hb, TSat, and ferritin monthly.c
If Hb increases appropriately (see text) continue ESA and consider maintenance iron (eg. daily PO iron for ND-CKD, weekly or monthly IV iron for ESKD) to avoid iron deficiency.
If Hb does not increase appropriately (see text) consider increase in ESA dose by 25% after evaluating for hyporesponsiveness. Avoid repeated escalation in ESA dose beyond double the initial weight-based dose. [2D]
If TSat and ferritin are below thresholds, give a course of iron (route and dose depend on CKD category and formulation). [2C]
Monitor Hb monthly (ESKD) or every 3 months (ND-CKD) Monitor TSat and ferritin at least every 3 months
If Hb does not increase appropriately (see text) consider increase in ESA dose by 25% after evaluating for hyporesponsiveness. Avoid repeated escalation in ESA dose beyond double the initial weight-based dose. [2D]
If TSat and ferritin are below thresholds, consider risk/benefit of a repeated course of IV iron (route and dose depend on CKD category and formulation).
Monitor Hb monthly (ESKD) or every 3 months (ND-CKD) Monitor TSat and ferritin at least every 3 months

Hypoxia-Inducible Factor Prolyl-Hydroxylase Inhibitors

A key target for anemia management in CKD is the development of HIF-prolyl-hydroxylase (HIF-PH) inhibitors or HIF stabilizers that mimic the conditions of hypoxia to prevent the hydroxylation process. The HIF-PH inhibitors in development in the United States include roxadustat, daprodustat, and vadadustat.[11,50] Demonstrated benefits include improvement in hemoglobin levels and induction of physiologic blood levels of erythropoietin. These agents also decrease hepcidin, increase iron absorption, and improve functional iron deficiency. There is some concern that long-term use of these agents and sustained HIF activation may promote tumor progression due to the effects on vascular endothelial growth factor and angiogenesis. While there remains much to learn about HIF-PH inhibitors, these agents are likely to become an integral therapy for anemia management in CKD.

Transfusions and Adjunct Therapies

Red blood cell transfusions carry many risks and therefore should only be used in select situations, such as acute management of symptomatic anemia, following significant acute blood loss, and prior to surgical procedures that carry a high risk of blood loss, with the goal of preventing inadequate tissue oxygenation or cardiac failure. L-carnitine supplementation and vitamin C were previously suggested as adjunctive treatments of CKD anemia, but are not recommended because of the lack of evidence supporting improved anemia management with these therapies.[14]

Evaluation of Therapeutic Outcomes

Important therapeutic outcomes to monitor in patients with anemia of CKD include Hb, iron status, as well as the need for blood transfusions. Iron status should be assessed at least every 3 months in patients receiving a stable ESA regimen.[14] Iron status should be monitored more frequently (eg, every month) when initiating or increasing the ESA dose, following a course of IV iron, or when other factors put the patient at risk for iron loss (eg, bleeding). Hb levels should be monitored at least every 3 months in patients with CKD not on dialysis or peritoneal dialysis patients and at least monthly in hemodialysis patients. Hb should be monitored at least monthly in patients started on ESA therapy until the Hb is stable. Of note, FDA labelling for ESAs recommends weekly monitoring of Hb with initiation of therapy or a change in dose until the Hb is stable.[44,47,49]

MINERAL AND BONE DISORDER

Management of PTH, phosphorus, and calcium is important in preventing CKD-MBD and CV and extravascular calcifications. Patients with CKD-MBD usually require a combination of dietary intervention, phosphate-binding medications, vitamin D, and calcimimetic therapy (for ESKD patients) to achieve these goals.

Desired Outcome

⑦The desired outcomes for management of CKD-MBD are to “normalize” the biochemical parameters and prevent bone manifestations, CV and extravascular calcifications, and the associated morbidity and mortality with both nonpharmacologic and pharmacologic interventions. At present, the 2017 KDIGO clinical practice guidelines for CKD-MBD are the most guidelines clinicians use in their patient care decision-making process.[17]

The KDIGO-recommended targets for calcium, phosphorus, and PTH and frequency of monitoring based on the CKD category are shown in Table 63-6.[17] The most appropriate strategy is to evaluate trends in all these key CKD-MBD parameters to determine a reasonable treatment approach. The guidelines emphasize to avoid hypercalcemia based on evidence linking higher calcium levels with mortality and nonfatal CV events. The recommendation for phosphorus is to maintain levels “toward normal” based on evidence linking both high and low phosphate concentrations with increased mortality. Despite this association with higher mortality, the effect of phosphorus lowering with therapy (ie, phosphate binders) has not consistently demonstrated improved hard outcomes such as reduced mortality.[51,52]

TABLE 63-6

KDIGO Monitoring and Goals for Calcium, Phosphorus, and Parathyroid Hormone

		Chronic Kidney Disease Stage		
Parameter	**G3**	**G4**	**G5**	**ESKD**
Corrected calcium[a] Monitoring frequency[b] Goal	Every 6-12 months Avoid hypercalcemia [2C]	Every 3-6 months Avoid hypercalcemia [2C]	Every 1-3 months Avoid hypercalcemia [2C]	Every 1-3 months Avoid hypercalcemia [2C]
Phosphorus Monitoring frequency[b] Goal	Every 6-12 months Toward the normal range [2C]	Every 3-6 months Toward the normal range [2C]	Every 1-3 months Toward the normal range [2C]	Every 1-3 months Toward the normal range [2C]
Intact PTH Monitoring frequency[b] Goal	Based on baseline level and CKD progression Avoid progressively rising levels or levels persistently above the upper limit of normal [2C]	Every 6-12 months Avoid progressively rising levels or levels persistently above the upper limit of normal [2C]	Every 3-6 months Avoid progressively rising levels or levels persistently above the upper limit of normal [2C]	Every 3-6 months 2-9 times the upper normal limit [2C]

Evidence grading in brackets.

[a] Corrected for albumin.

[b] Not graded.

Data from Reference 9.

Clinicians involved in the care of patients with CKD should know which PTH assays are available in their facilities. PTH is secreted from the parathyroid gland as intact PTH, an 84-amino-acid peptide chain (1-84 PTH) that is biologically active, and as smaller carboxy-terminal PTH fragments.[53] Circulating levels of these fragments (eg, 7-84 PTH) may increase substantially in patients with CKD and actively antagonize the effects of 1 to 84 PTH. The available immunoradiometric assays measure not only the intact PTH molecule but also fragments, which may lead to overestimation of biologically active PTH. While correction factors have been proposed, they cannot be uniformly applied to all commercially available assays and thus inconsistent results are common. The variability in PTH measurements and lack of evidence to support a specific target are part of the rationale for the KDIGO recommendation to monitor trends in serum PTH to guide treatment decisions. The optimal PTH in patients with CKD stages G3a-G5 is unclear. An increase in PTH is expected in response to declining kidney function and the desired phosphaturic effects; therefore, the guidelines specify that PTH levels *persistently* above the upper limit of normal and *progressively rising* should warrant a treatment decision. KDIGO recommends that PTH values for ESKD patients be within two to nine times the upper limit of the normal range, which corresponds to a PTH of approximately 130 to 600 pg/mL (ng/L; 14-64 pmol/L).[17] PTH values above 600 pg/mL (ng/L; 64 pmol/L) have been associated with higher CV mortality and hospitalizations.[54]

Monitoring of alkaline phosphatase activity is also recommended as this test may serve as a gauge of a patient's response to therapy and/or bone turnover status. Avoiding the development of vascular calcification, and calciphylaxis is also important as treatment options for this complication once it develops are extremely limited and the associated mortality is high.

Nonpharmacologic Therapy

Dietary Phosphorus Restriction

Dietary phosphorus restriction is a first-line intervention for management of hyperphosphatemia and should be initiated for most patients with CKD G3-G5.[17] The challenge with dietary restriction of phosphorus is providing enough protein to prevent malnutrition, a common problem in the ESKD population because dialysis patients require a higher protein intake (1.2-1.3 g/kg/day) and foods high in phosphorus are generally high in protein. An additional consideration is the source of phosphorus, organic versus inorganic. Inorganic sources such as from frozen meals and processed foods include preservatives or additives used during food processing, whereas organic sources such as from meat and plant sources typically do not and may be a better option. Dietary supplements and certain brands of medications also contain phosphate (eg, amlodipine, codeine) and may contribute to phosphate intake.[55] One of the most common obstacles to dietary phosphorus restriction is patient nonadherence because of the poor palatability of the allowed foods. Regular counseling by a dietitian is ideal to design a realistic diet that works with the patient's lifestyle and considers nutritional goals.

Dialysis

HD and PD lower serum phosphorus and calcium, the extent of which is dependent on the concentration of each in the dialysate and the duration of dialysis. It is suggested that the dialysate calcium concentration be between 2.5 and 3 mEq/L (1.25 and 1.5 mmol/L).[17] Removal of phosphorus does occur with dialysis (~2.5-3.5 g/wk, dependent on the dialysis prescription); however, conventional dialysis alone does not usually control hyperphosphatemia.[56] Patients on daily HD or nocturnal HD who typically have longer and/or more frequent dialysis sessions have better phosphorus control and require fewer phosphate-binding agents and in some cases may even require phosphate supplementation.

Parathyroidectomy

Parathyroidectomy is a therapeutic option for those patients with persistently elevated PTH associated with hypercalcemia and/or hyperphosphatemia who are refractory to medical therapy (a grade 2B recommendation).[17] Surgical approaches include either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to an accessible site, such as the forearm. Postoperative hypocalcemia, hypophosphatemia, and hypomagnesemia may occur because of a marked increase in bone production in relation to bone absorption (“hungry bone syndrome”). Following surgery, frequent monitoring of calcium and phosphorus is necessary. Treatment with supplemental calcium and vitamin D may be required for weeks or months.

While a parathyroidectomy is indicated for refractory patients, these patients may experience significant morbidity following the procedure. In a study of over 4,400 ESKD patients who underwent a parathyroidectomy, there was an increase in hospitalizations (particularly for acute myocardial infarction and dysrhythmia) and emergency room visits for treatment of hypocalcemia in the year following the procedure.[57] For some patients, a parathyroidectomy may be ineffective and there is also the risk of over suppression of PTH and prolonged hypocalcemia.[58]

Pharmacologic Therapy

Patients with CKD-MBD usually require a combination of dietary intervention, phosphate-binding medications, vitamin D, and calcimimetic therapy (for ESKD patients).

Phosphate-Binding Agents

Phosphate-binding agents are used in addition to dietary phosphorus restriction to limit GI absorption. These agents are indicated for CKD patients with progressive or persistent hyperphosphatemia. For many patients, the pill burden with phosphate-binding agents contributes to nonadherence and efforts should be made to simplify the regimen when possible. The cost of phosphate binders is also significant, contributing to over 1.5 billion in Medicare costs for US dialysis patients and CKD patients with Medicare Part D.[52]

Pharmacology and Mechanism of Action

Drugs that bind dietary phosphorous in the GI tract form insoluble phosphate compounds that are excreted in feces, thus reducing dietary phosphorus absorption. Patients must be instructed to take these agents with meals to maximize the binding of phosphorus from dietary sources. A variety of phosphate-binding agents with varying binding affinity are available including elemental calcium, iron, and lanthanum-containing compounds, and the nonelemental agent sevelamer (Table 63-7). Estimates of phosphate-binding equivalent doses relative to 1 g of calcium carbonate have been reported based on the commonly available tablet or capsule strengths of each binder (calcium acetate 667 mg = 0.67; lanthanum 500 mg = 1.0, sevelamer carbonate 0.60, sucroferric oxyhydroxide 500 mg = 1.6, ferric citrate 210 mg = 0.64, aluminum hydroxide 500 mg = 0.75, and aluminum carbonate 500 mg = 0.95).[52,59] These values have been applied to estimate a phosphate binder equivalent dose.

TABLE 63-7

Phosphate-Binding Agents for Treatment of Hyperphosphatemia in Chronic Kidney Disease Patients

Category	Drug	Brand Name	Compound Content	Starting Doses	Dose Titration[a]	Comments[b]
Calcium-based binders	Calcium acetate (25% elemental calcium)	PhosLo	25% Elemental calcium (169 mg elemental calcium per 667 mg capsule)	1,334 mg three times a day with meals	Increase or decrease by 667 mg meal (169 mg elemental calcium)	Comparable efficacy to calcium carbonate with lower dose of elemental calcium Approximately 45 mg phosphorus bound per 1 g calcium acetate Evaluate for drug interactions with calcium
		Phoslyra	667 mg calcium acetate per 5 mL			
	Calcium carbonate[c]	Tums, Os-Cal, Caltrate	40% Elemental calcium	0.5-1 g (elemental calcium) three times a day with meals	Increase or decrease by 500 mg/meal (200 mg elemental calcium)	Dissolution characteristics and phosphate binding may vary from product to product Approximately 39 mg phosphorus bound per 1 g calcium carbonate Evaluate for drug interactions with calcium
Iron-based binders	Ferric citrate	Auryxia	210 mg elemental iron per tablet (= 1 g ferric citrate)	420 mg ferric iron three times daily with meals	Increase or decrease dose by 1 or 2 tablets per meal	May increase serum iron, ferritin, and TSat May cause discolored (dark) stools Evaluate for drug interactions with iron
	Sucroferric	Velphoro	500 mg	500 mg three	Increase or	May cause discolored

	oxyhydroxide		elemental iron per chewable tablet (=2.5 g succroferric oxyhydroxide)	times daily with meals	decrease by 500 mg/day	(dark) stools Evaluate for drug interactions with iron
Resin binders	Sevelamer carbonate	Renvela	800 mg tablet 0.8 and 2.4 g powder for oral suspension	800-1,600 mg three times a day with meals (once-daily dosing also effective)	Increase or decrease by 800 mg/meal	Also lowers low-density lipoprotein cholesterol Consider in patients at risk for extraskeletal calcification Risk of metabolic acidosis with sevelamer hydrochloride (less risk with carbonate formulation) May interact with cipro and mycophenolate mofetil
	Sevelamer hydrochloride	Renagel	400 and 800 mg caplets	800-1,600 mg three times a day with meals	Increase or decrease by 800 mg/meal	
Other elemental binders	Lanthanum carbonate	Fosrenol	500, 750, and 1,000 mg chewable tablets 750 and 1,000 mg oral powder	1,500 mg daily in divided doses with meals	Increase or decrease by 750 mg/day	Potential for accumulation of lanthanum due to GI absorption (long-term consequences unknown) Evaluate for drug interactions (eg, cationic antacids, quinolone antibiotics)
	Aluminum hydroxide (NOT PREFERRED)	AlternaGel	Content varies (range 100-600 mg/unit)	300-600 mg three times a day with meals	Not for long-term use requiring titration	Not a first-line agent; risk of aluminum toxicity; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to

						other binders Evaluate for drug interactions

TSat, transferrin saturation.

[a] Based on phosphorus levels, titrate every 2 to 3 weeks until phosphorus goal reached.

[b] GI side effects are possible with all agents (eg, nausea, vomiting, abdominal pain, diarrhea, or constipation).

[c] Multiple preparations available that are not listed.

Efficacy

Oral calcium compounds are commonly used agents for control of serum phosphorus. Calcium carbonate and calcium acetate are the primary preparations used. Calcium citrate is also available but not used as a binder since the citrate component increases aluminum absorption and may cause more GI side effects. Calcium carbonate is marketed in a variety of dosage forms and is relatively inexpensive. Unfortunately, many calcium carbonate products are considered food supplements and thus do not meet US Pharmacopeia (USP) disintegration and dissolution requirements. In general, nationally advertised brands do meet these requirements, but it is difficult to determine whether private labels or house brands conform to these standards. Variability in gastric pH may also affect disintegration or dissolution, and thus phosphate-binding efficacy. Calcium carbonate is more soluble in an acidic medium and should be administered prior to meals when stomach acidity is highest. In addition, acid-suppressing agents such as ranitidine and proton pump inhibitors may reduce the phosphate-binding activity of calcium carbonate by increasing gastric pH. For patients with hypocalcemia, calcium carbonate or calcium acetate may also be given as a calcium supplement taken between meals to promote calcium absorption. This is a common scenario for patients following a parathyroidectomy.

Sevelamer is a nonabsorbable, nonelemental hydrogel phosphate-binding agent approved for ESKD patients, which effectively lowers phosphorus and has also been shown to lower LDL and increase HDL cholesterol. Sevelamer hydrochloride carries the risk of metabolic acidosis, a problem that has been overcome with development of the carbonate formulation. Sevelamer carbonate also comes in a powder formulation, which is a good option for many patients unable to swallow tablets.

Most of the comparative studies to date have focused on calcium-based binders versus sevelamer, which was the first non-calcium binder made available in the United States. The chronic use of calcium-containing phosphate binders promotes progression of vascular calcification; however, not all studies support this finding and this effect may occur with non-calcium–containing binders as well.[52] Available studies have more consistently shown a significant increase in coronary artery calcification with calcium-containing binders compared to sevelamer.[60] The effect of binder choice on mortality, particularly on CV mortality, is also controversial as studies evaluating this outcome are limited. Results of a meta-analysis showed that all cause death and risk of hypercalcemia were lower in dialysis patients receiving sevelamer when compared with calcium-based binders.[51] Fatal and nonfatal cardiovascular events, however, did not differ for ESKD patients receiving sevelamer compared to calcium acetate in an observational cohort study.[61] KDIGO suggests restricting the dose of calcium-based binders (a grade 2B recommendation); however, a maximum dose was not defined and this is left to clinical judgement.[17]

Lanthanum carbonate is a phosphate binder approved for patients with ESKD and has demonstrated efficacy in controlling phosphorus and maintaining PTH in the target range with less risk of hypercalcemia than calcium-containing binders.[17] The initial daily dose of 1,500 mg (administered in divided doses with meals) is often titrated to a range of 1,500 to 3,000 mg to maintain target phosphorus. The poor GI absorption, which limits systemic effects, and high binding capacity with phosphorus make this an attractive phosphate-binding agent, particularly when calcium-containing binders are not recommended due to hypercalcemia. Lanthanum is available as a chewable tablet, which may be appealing for some patients.

Ferric citrate and sucroferric oxyhydroxide are the newest iron-based phosphate-binding agents approved for ESKD patients. Sucroferric oxyhydroxide effectively lowers phosphorus over a long-term (1-year) period and may have a lower pill burden compared to other agents.[62] It is also available as a chewable tablet. Ferric citrate effectively lowers phosphorus and also offers the advantage of increasing iron indices (TSat and ferritin) while lowering IV iron and ESA use when compared to other binders and ferrous sulfate.[63–65] This agent is approved as for treatment of both hyperphosphatemia in ESKD patients and for iron deficiency anemia in patients with CKD not on dialysis. Another potential advantage of ferric citrate (and of iron supplementation in general) being explored is reduction in FGF23 that has been observed.[64] This finding is of interest given the associated between FGF23 and adverse outcomes.

Aluminum salts were widely used in the 1980s as phosphate-binding agents because of their high binding potency. Due to the potential for accumulation and toxicities in patients with CKD, they should not be used as first-line agents. KDIGO recommends avoiding the long-term use of aluminum-containing binders in all patients with CKD stage G3a-G5D (a 1C recommendation).[17]

Magnesium-containing antacids are also effective phosphate binders and may decrease the amount of calcium-containing binders necessary for control of phosphorus; however, they are not preferred due to the frequent occurrence of GI side effects (ie, diarrhea) and the potential for magnesium accumulation.

Other agents that have been evaluated for their phosphate binding effects and potential use for prevention and treatment of hyperphosphatemia in CKD patients include nicotinamide and tenapanor. Nicotinamide is a metabolite of nicotinic acid that inhibits the gastrointestinal sodium-dependent phosphate transporter, NaPi2b. This agent has been studied in hemodialysis patients with some promising results in terms of phosphorus lowering effects; however, lack of robust clinical data to support consistent phosphate lowering and adverse effects may limit effectiveness and tolerability.[66–68] Tenapanor is an inhibitor of intestinal sodium/hydrogen exchanger 3 (NHE3) that blocks paracellular transport of phosphate across the intestinal lumen. This agent is approved for treatment of irritable bowel syndrome with constipation, but has also been studied in hemodialysis patients as a single agent and as an add on therapy to current phosphate binder treatments.[69–71] Phosphate lowering effects have been consistently demonstrated with diarrhea as the most frequent adverse effect. In 2021, the FDA did not grant approval of this agent for control of phosphorus in dialysis patients due to what was considered a small treatment effect with unclear clinical significance.

Adverse Effects

Adverse effects of all available phosphate binders are generally limited to constipation, diarrhea, nausea, vomiting, and abdominal pain. The risk of hypercalcemia may necessitate restriction of calcium-containing binder use and/or a reduction in dietary intake. Aluminum binders have been associated with CNS toxicity and the worsening of anemia, whereas magnesium binder use may lead to hypermagnesemia and hyperkalemia; therefore, aluminum and magnesium are not recommended for regular use in patients with kidney disease. The potential for iron overload should also be considered with ferric citrate given the effects on increasing iron indices. Accumulation of lanthanum tablets in the GI tract of a patient who swallowed these tablets resulted in severe complications; therefore, counsel patients to chew these tablets.[72] The same counseling point applies for sucroferric oxyhydroxide.

Drug-Drug and Drug-Food Interactions

Calcium-containing phosphate-binding agents interfere with the absorption of several oral medications that are commonly prescribed for CKD patients, including iron, zinc, and quinolone antibiotics. Coadministration of sevelamer with ciprofloxacin and mycophenolate did result in a reduction in bioavailability of these agents and they should be taken at least 2 hours before sevelamer. Coadministration of lanthanum with tetracyclines, fluoroquinolones, levothyroxine, or drugs known to bind with cationic antacids may result in decreased bioavailability of these agents. The iron-containing products ferric citrate and sucroferric oxyhydroxide also have the potential for drug interactions due to the iron component. In general, it is rational to separate the administration time of oral medications for which a reduction in bioavailability has a clinically significant effect (eg, quinolones) from phosphate binders by at least 1 hour before or 3 hours after administration of the phosphate binder. Many phosphate binders are marketed as antacids or calcium supplements, and often CKD patients do not know why they have been prescribed these agents. Regular patient counseling is essential to improve adherence and minimize the potential for drug interactions.

Dosing and Administration

Initial dosing regimens for phosphate-binding agents and suggested dose titration schemes are shown in Table 63-7. Doses should be titrated to achieve the recommended serum phosphorus concentrations in conjunction with dietary intervention and dialysis (for ESKD patients).

Vitamin D Therapy

Vitamin D compounds available in the United States include nutritional vitamin D (ergocalciferol [D_2] and cholecalciferol [D_3]), the prohormone calcifediol [25(OH)D_3], active vitamin D (calcitriol [D_3]), and vitamin D analogs (paricalcitol and doxercalciferol [both D_2]) (Table 63-8). Nutritional vitamin D (NVD) is derived from dietary plant (D_2) and animal (D_3) sources, or from supplements. While this chapter focuses on the role of NVD and FDA-approved vitamin D formulations for the management of mineral homeostasis, there are several other therapeutic uses for vitamin D (eg, for CV and immune-related effects) and other analogs available outside the United States which are not discussed (eg, alfacalcidol).

TABLE 63-8

Vitamin D Agents

Generic Name	Brand Name	Form of Vitamin D	Dosage Forms	Initial Dose	Dosage Range	Frequency of Dosing or Dose Titration[a]
Nutritional Vitamin D						
Ergocalciferol	Drisdol	D_2	po	Varies based on 25(OH)D levels	400-50,000 international units	Daily (doses of 400-2,000 international units)
Cholecalciferol[b]	Generic	D_3	po			Weekly or monthly for higher doses (50,000 international units)
Calcifediol Rayaldee D_3 po 30 μg daily 30-60 μg Increase after 3 months if PTH above desired range						
Vitamin D and Analogs						
Generic Name	**Brand Name**	**Form of Vitamin D**	**Dosage Forms**	**Initial Dose[c,d]**	**Dosage Range**	**Dose Titration[a]**
Calcitriol	Rocaltrol	D_3	po	0.25 μg daily	0.25-5 μg	Increase by 0.25 μg/day at 4-8 week intervals
	Calcijex		IV	1-2 μg three times per week	0.5-5 μg	Increase by 0.5-1 μg at 2 to 4 week intervals
Doxercalciferol[e]	Hectorol	D_2	po	ND-CKD: 1 μg daily	5-20 μg	Increase by 0.5 μg at 2-week intervals for daily dosing or by 2.5 μg at 8-week intervals for three times per week dosing
				ESKD: 10 μg three times per week		
			IV	ESKD: 4 μg three times per week	2-8 μg	Increase by 1-2 μg at 8-week intervals
Paricalcitol	Zemplar	D_2	po	ND-CKD: 1 μg daily or 2 μg three times per week if PTH ≤500 pg/mL (ng/L; 54 pmol/L); 2 μg daily or 4 μg three times per week if PTH >500 pg/mL (ng/L; 54 pmol/L)	1-4 μg	Increase by 1 μg (for daily dosing) or 2 μg (for three times per week dosing) at 2-4 week intervals
			IV	ESKD: 0.04-1 μg three times per week	2.5-15 μg	Increase by 2-4 μg at 2-4 week intervals

ESKD, end-stage kidney disease; ND-CKD, non-dialysis chronic kidney disease; PTH, parathyroid hormone.

[a] Based on PTH, calcium and phosphorus levels. Decreases in dose are necessary if PTH is oversuppressed and/or if calcium and phosphorus are elevated.

[b] Multiple preparations are available that are not listed.

[c] Dose ratios are as follows: 1:1 for IV paricalcitol to oral doxercalciferol, 1.5:1 for IV paricalcitol to IV doxercalciferol, and 1:1 for IV to oral calcitriol.

[d] Daily orally dosing most common for non-hemodialysis CKD patients, IV dosing three times per week more often used in the hemodialysis population.

[e] Prodrug that requires activation by the liver.

Pharmacology and Mechanism of Action

Vitamin D is a cholesterol derivative and is transported in the circulation by vitamin D–binding protein. The process of vitamin D metabolism is shown in Fig. 63-3. Both endogenously synthesized D_3 and NVD compounds (as D_2 or D_3) are converted in the liver to 25(OH)D, by the 25-hydroxylase enzyme. The 25(OH)D form is subsequently converted to the biologically active form 1,25-dihydroxyvitamin D (either D_2 or D_3 depending on the parent compound) by the 1-α-hydroxylase enzyme. This conversion occurs primarily in the kidney, but this enzyme is also present in extrarenal tissues. It is not clear whether active vitamin D produced in extrarenal tissue exerts its effects only locally or contributes to the systemic endocrine functions. It is the concentration of 25(OH)D that is most commonly measured clinically to diagnose vitamin D deficiency. The 25(OH)D form is available as calcifediol, an extended release oral formulation of the prohormone, indicated for patients with CKD G3 or G4 with low 25(OH)D levels (< 30 ng/mL [75 nmol/L]).

Calcitriol and the vitamin D analogs bind to the vitamin D receptors (VDRs), which are located in many organ systems including the parathyroid glands, intestine, bone, kidney, heart, nervous, and immune systems. When vitamin D binds to the VDR, there is a conformational change in the VDR that allows for interaction of the receptor with the retinoid X receptor (RXR), a transcriptional factor.[73] The VDR-RXR complex binds to DNA sequences in target genes to either promote or inhibit transcription depending on the organ system. Vitamin D inhibits or suppresses PTH synthesis and also stimulates absorption of serum calcium by intestinal cells. As a result, the serum calcium concentration is raised, which decreases PTH secretion by the parathyroid glands. The set point for calcium (ie, the calcium concentration at which PTH secretion is decreased by 50%), which is generally raised in those with CKD-MBD, is lowered when active vitamin D therapy is initiated. This results in a lower ionized calcium concentration becoming effective at suppressing secretion of PTH. Unfortunately, the enhanced GI absorption of calcium and phosphorus associated with calcitriol therapy may lead to hypercalcemia and hyperphosphatemia, which are associated with soft-tissue and vascular calcifications.

The unique interactions of vitamin D with the VDRs have led to the development of vitamin D analogs that vary in their affinity for the VDRs. Paricalcitol and doxercalciferol retain activity with vitamin D receptors on the parathyroid gland to effectively lower PTH, but have less risk of hypercalcemia and hyperphosphatemia due to their lower intestinal activity. Paricalcitol differs from calcitriol by the absence of the exocyclic carbon 19 and the fact that it is a vitamin D_2 derivative (19-nor-1,25-dihydroxyvitamin D_2). This compound is active as given. Doxercalciferol, however, is a prohormone that does require activation by CYP27 in the liver to form the major active D_2 metabolite 1,25-dihydroxyvitamin D_2 (see Fig. 63-3).

Pharmacokinetics

Oral absorption of calcitriol occurs rapidly; therefore, both oral and IV therapies are reasonable options for treatment of CKD-MBD. The half-life of active calcitriol ranges from 15 to 38 hours in patients with ESKD.[74] The half-lives of paricalcitol and doxercalciferol are approximately 15 hours and 32 to 37 hours, respectively.[75,76] These agents are extensively bound to plasma proteins and not removed by dialysis.

Efficacy

Calcitriol, paricalcitol, and doxercalciferol are all effective in lowering PTH in patients with CKD; however, the trade-off is the undesired effect of raising calcium and phosphorus concentrations due to increased intestinal absorption. Although these effects are less likely with paricalcitol and doxercalciferol, elevated calcium concentrations have been observed. An all-cause and CV survival benefit has also been reported with these agents in both CKD and ESKD patients in observational studies.[77] These survival benefits, however, have not been substantiated in randomized clinical trials based on meta-analysis of available data.[78] KDIGO does not advocate for routine use of calcitriol and vitamin D analogs in the non-dialysis CKD population (a 2C recommendation) and suggests that they be reserved for patients with CKD stages G4-G5 (a recommendation that was not graded). These agents may be used in conjunction with calcimimetics when warranted in the dialysis population (a 2B recommendation).

A review and meta-analysis in CKD patients (including ESKD patients) reported that NVD supplementation was associated with an improvement in 25(OH)D levels and decreased PTH without significant hypercalcemia or hyperphosphatemia in nondialysis CKD patients;[79] however, this has not been a consistent finding. In ESKD patients, NVD has resulted in increased levels of 25(OH)D and a decrease in PTH, which suggests a potential role of extrarenal pathways of vitamin D activation; however, these patients typically also require active vitamin D or analog therapy. Calcifediol has been shown to lower PTH with relatively minimal effects on serum calcium and phosphorus in stage G3-G4 CKD, which is the reason it has gained approval in non-dialysis CKD patients to treat 25(OH)D deficiency.[80] The survival benefit of correcting vitamin D deficiency with NVD in the CKD population is unknown. The recommendation by KDIGO is that confirmed 25(OH)D deficiency in patients with CKD G3a-G5D be corrected using treatment strategies in the general population (a 2C recommendation), which includes NVD therapies.[17,81]

Adverse Effects

Although all agents are effective in suppressing PTH, they may cause hypercalcemia and hyperphosphatemia, an effect that is most likely with calcitriol. Oversuppression of PTH and inducement of adynamic bone disease are also distinct possibilities.

Drug-Drug and Drug-Food Interactions

Cholestyramine may reduce the absorption of orally administered calcitriol and doxercalciferol. In vitro data suggest that paricalcitol is metabolized by the hepatic enzyme CYP3A4 and thus it has the potential to interact with other agents that are metabolized by this enzyme. Caution is also advised when CYP3A4 inhibitors are given to those receiving doxercalciferol since hydroxylation of this precursor agent may be inhibited.

Dosing and Administration

Despite limited evidence, KDIGO guidelines support administering NVD to patients with CKD G3a-G5 and ESKD with vitamin D deficiency or insufficiency (a grade 2C recommendation).[17] Calcitriol, doxercalciferol, or paricalcitol should be administered when PTH remains elevated despite the achievement of adequate 25(OH)D levels. ESKD patients require calcitriol, doxercalciferol, or paricalcitol.

Calcitriol by either the oral or the IV route may be administered daily (usually 0.25-1 μg/day) or using a pulse dosing (0.5-2 μg 2 to 3 times/wk) approach. Recommended doses of available NVD and analogs and suggested dose titration schemes are shown in Table 63-8. Prior to starting therapy, the serum calcium and phosphorus should be within the normal range. This does not mean that vitamin D therapy should be withheld or discontinued in all patients with elevated calcium and phosphorus values, but rather that use of agents with a lower risk of hypercalcemia and hyperphosphatemia and more prudent use of phosphate binders to lower calcium and phosphorus may be necessary in such patients. Dose adjustments of vitamin D should be made every 2 to 4 weeks based on PTH concentrations and trends in calcium and phosphorus.

Calcimimetics

Cinacalcet hydrochloride (Sensipar) and etelcalcetide (Parsabiv) are calcimimetic agents approved for treatment of secondary hyperparathyroidism in CKD patients on dialysis. Cinacalcet is available as an oral agent, whereas etelcalcetide is an IV formulation. Both agents are approved for use only in dialysis patients.

Pharmacology and Mechanism of Action

Cinacalcet and etelcalcetide work through their interactions on the calcium-sensing receptor (CSR) located on the surface of the chief cells of the parathyroid gland. Cinacalcet works as an allosteric modulator of the CSR though binding to the transmembrane domain of the receptor while etelcalcetide binds directly to the extracellular domain resulting in increased sensitivity of the receptor to extracellular calcium (ie,, lowering the threshold for receptor activation by calcium) and subsequently reducing PTH secretion.[82]

Pharmacokinetics

Cinacalcet peak concentrations are observed 2 to 6 hours following oral administration. Its elimination half-life is approximately 30 to 40 hours and steady state plasma concentrations are achieved in approximately 7 days. It has a large volume of distribution (~1,000 L) and is 93% to 97% bound to plasma proteins, thus removal by dialysis is negligible. Cinacalcet is metabolized by the liver, specifically by the cytochrome P450 isoenzymes CYP3A4, CYP2D6, and CYP1A2.[83] Etelcalcetide has a half-life of 3 to 4 days and plasma levels reach steady state in several weeks.[84] This agent is not metabolized by CYP isoenzymes, but is cleared by renal excretion. Unlike cinacalcet this agent is cleared by hemodialysis.

Efficacy

In clinical trials conducted predominantly in dialysis patients, cinacalcet significantly decreased PTH, calcium, and phosphorus, regardless of the severity of secondary hyperparathyroidism. In non-dialysis CKD patients cinacalcet reduced PTH, but was associated with a high incidence of hypocalcemia and hyperphosphatemia; thus, this agent is not approved for use in non-dialysis CKD patients. Cinacalcet may be used as a single agent to control hyperparathyroidism in ESKD patients; however, combined therapy with vitamin D is often necessary to achieve target PTH, calcium, and phosphorus values. In the ADVANCE trial, cinacalcet plus low-dose active vitamin D increased coronary artery calcification scores but to a lesser degree than its comparator calcitriol alone.[85] A decrease in all-cause and CV mortality was also suggested by results of an observational study in HD patients prescribed cinacalcet in addition to vitamin D compared with those on vitamin D alone.[86] While these findings were promising, they were not supported by the EVOLVE trial (the Evaluation of Cinacalcet Therapy to Lower CV Events), a prospective study which revealed that cinacalcet did not significantly reduce the risk of all-cause mortality or major CV events in patients with CKD 5HD.[87] There has been much debate with regard to the design and analysis of the EVOVLE trial and the interpretation of the findings with subsequent sub analyses of the data to evaluate other outcomes such reduction in FGF23 and risk of hypocalcemia.[88–90]

Etelcalcetide is effective in lowering PTH in hemodialysis patients with more long term data (up to 12 months) showing sustained efficacy and safety.[91–93] Like cinacalcet, this agent also lowers calcium and phosphorus but has also been shown to lower FGF23 to a greater extent.[91,94,95] There have not been clinical studies to evaluate the effect of etelcalcetide on mortality or cardiovascular events; however, a small study in HD patients did show improvement in left ventricular hypertrophy that was associated with FGF23 lowering effects.[96]

Adverse Effects

The most frequent adverse events associated with cinacalcet are nausea and vomiting, which may account for nonadherence. Nausea and vomiting were reported with etelcalcetide in both the placebo-controlled trials and in the comparison trial with cinacalcet at a rate that was not significantly different compared with cinacalcet.[91,97] Since these agents lower serum calcium they should not be started if the corrected serum calcium is less than the lower limit of normal, approximately 8.4 mg/dL (2.10 mmol/L). Serum calcium should be measured within 1 week after initiation or following a dose adjustment. Once the maintenance dose is established, serum calcium should be measured monthly. Potential manifestations of hypocalcemia include paresthesia, myalgia, cramping, tetany, and convulsions. Hypocalcemia may also lead to Q-T interval prolongation and ventricular arrhythmias, which further emphasizes the importance of regular calcium monitoring.

Drug-Drug and Drug-Food Interactions

Because cinacalcet is partially metabolized by CYP3A4, there is potential for drug interactions with agents that inhibit this pathway. Coadministration of cinacalcet and ketoconazole, a strong inhibitor of CYP3A4, result in a twofold increase in the area under the curve and maximum concentration. Cinacalcet is also a potent inhibitor of CYP2D6. As a result, dose adjustments of concomitant medications that are predominantly metabolized by this enzyme and have a narrow therapeutic index, such as flecainide, thioridazine, vinblastine, and most tricyclic antidepressants (eg, amitriptyline, desipramine), may be necessary. Concurrent administration of cinacalcet with desipramine increased exposure by approximately 260% in CYP2D6-extensive metabolizers.[83] Food has been shown to increase absorption of cinacalcet by up to 82% compared with fasting; therefore, this medication should be taken with meals to achieve the maximal effect.

There are no drug interactions reported with etelcalcetide. Of note, this agent is not a substrate or inhibitor of CYP isoenzymes or transporter proteins (eg, *P*-glycoprotein, organic anionic/cationic transporters).

Dosing and Administration

The recommended starting dose of cinacalcet is 30 mg orally once daily. Calcium and phosphorus should be measured at 1 week and PTH should be measured within 1 to 4 weeks after starting cinacalcet or adjusting the dose. The dose should be titrated every 2 to 4 weeks to a maximum dose of 180 mg once daily until the desired PTH values are achieved and to maintain goal serum calcium concentrations. Patients with hepatic disease may require lower doses, since the cinacalcet half-life is approximately doubled in those with severe liver disease.[83] Cinacalcet is available as film-coated tablets containing 30, 60, or 90 mg.

Etelcalcetide should be initiated at a dose of 5 mg administered intravenously three times per week at the end of the hemodialysis treatment. Calcium and phosphorus should be measured 1 week after initiation and then every 4 weeks for maintenance therapy. PTH levels should be measured 4 weeks after initiation and then per protocol based on the practices of the dialysis center. If PTH levels are above the recommended target range and the corrected serum calcium is within the normal range, the dose of etelcalcetide should be increased in 2.5 or 5 mg increments up to a maximum dose of 15 mg. The dose should be decreased or temporarily discontinued in patients with PTH levels below the target range or in patients with a corrected calcium at or above 7.5 mg/dL (1.88 mmol/L) without symptoms of hypocalcemia. Other interventions to increase calcium may be initiated if necessary (eg, altering vitamin D therapy and calcium supplementation). Etelcalcetide may be resumed once the PTH is within the target range and hypocalcemia has resolved, but at a lower dose. If the corrected calcium is below 7.5 mg/dL (1.88 mmol/L), then etalcalcitide should be discontinued and reinitiated at a dose 5 mg lower than the last administered dose once hypocalcemia has resolved. Patients who were receiving 2.5 or 5 mg should be reinitiate therapy at a dose of 2.5 mg.[84]

Since etelcalcetide is removed by hemodialysis it should be administered at the end of the hemodialysis treatment and injected into the venous line of the dialysis circuit during or after rinse back. If a dose is missed (eg, due to a missed hemodialysis treatment), then that missed dose should not be administered, but the patient should resume the regular treatment schedule at the next hemodialysis session. If doses are missed for more than 2 weeks, then etelcalcetide should be restarted at the 5 mg dose.[84] If switching a patient from cinacalcet to etelcalcetide, then cinacalcet should be discontinued for at least 7 days prior to starting etelcalcetide. If switching patients from etelcalcetide to cinacalcet, etalcalcetide should be discontinued for at least 4 weeks prior to starting cinacalcet due to the long half-life of etalcalcetide.

Cardiovascular Complications of Chronic Kidney Disease

Cardiovascular Disease

Patients with CKD are at increased risk of CVD, independent of the etiology of their kidney disease. This greater burden of CVD in patients with CKD is illustrated in Fig. 63-5.[3] The prevalence of any form of CVD is greater as kidney disease progresses from CKD stages G1-G5 (Fig. 63-5a) and is highest in patients with ESKD (Fig. 63-5b). This burden of CVD is associated with much higher mortality rates. In general, CKD patients have a lower probability of survival for all of the CVD conditions reported, with late stages of CKD being associated with the worst outcomes.[98] For example, the adjusted 2-year survival probability for patients with an AMI without a diagnosis of CKD is 71% versus 60% for CKD Stage 1 to 2 patients and 54% for CKD Stage 4 to 5 patients.[3] In addition to traditional risk factors for CVD such as diabetes mellitus/insulin resistance, dyslipidemia, hypertension, LVH, smoking, and obesity patients with CKD have other nontraditional risk factors including proteinuria, inflammation, anemia, and abnormal calcium and phosphate metabolism resulting in vascular calcification and oxidative stress.[98,99]

FIGURE 63-5

Prevalence of cardiovascular diseases in (A) Medicare patients ≥ 66 years by CKD status and stage, 2018 and (B) patients with ESKD by treatment modality.[3] (AF, atrial fibrillation; AMI, acute myocardial infarction; CAD, coronary artery disease; CKD, chronic kidney disease; CVA/TIA, cerebrovascular accident/transient ischemic attack; CVD, cardiovascular disease; HD, hemodialysis; HF, heart failure; KTx, kidney transplant; PAD, peripheral arterial disease; PD, peritoneal dialysis; SCA/VA, sudden cardiac arrest and ventricular arrhythmias; VHD, valvular heart disease; VTE/PE, venous thromboembolism and pulmonary embolism. (*Medicare 5% sample of patients aged 66 years and older, alive, without ESKD, and residing in the United States on 12/31/2018. Note: The data reported here have been supplied by the United States Renal Data System [USRDS].*)

Unfortunately, the lack of randomized trials treating CVD in patients with CKD often leads to treatment decisions that are based on extrapolation from trials in non-CKD populations and from observational data in CKD patients and not robust evidence. Treatment approaches for CVD include strategies to mitigate the traditional and non-traditional risk factors for CVD. The lack of data specific to CKD is a reason for the absence of guidelines on management of CVD in patients with CKD. The 2013 KDIGO CKD guideline did include statement regarding select CVDs including ischemic heart disease and recommended that the level of care for ischemic heart disease offered to people with CKD should not differ from people without CKD (grade 1A recommendation) as the treatment of traditional risk factors in CKD patients is of benefit.[100] These patients should also receive the standard assessments and treatments such as statins for CKD 1-5 (non-dialysis), beta-blockers, ACEIs/ARBs, and antiplatelet agents (see Chapters 33 and 34). Clinicians should note that in the diagnosis of acute coronary syndrome, elevated serum troponins should be interpreted with caution in individuals with a GFR less than 60 mL/min/1.73 m^2 (<0.58 mL/s/m^2) because these markers are often elevated as a result of reduced renal excretion (a grade 1B recommendation).

With regard to heart failure, KDIGO suggested that patients with CKD should receive standard heart failure therapies (Chapter 36); however, clinicians should be aware that RAAS blockade (eg, ACEI, ARB, neprilysin inhibitor/ARB, spironolactone, eplerenone) and diuretic therapy (eg, furosemide, metolazone) may lead to significant changes in GFR and serum potassium concentrations. Such therapy should not be avoided, but closely monitored and put into the context of individual risks and benefits. With regard to the cardiac biomarkers of B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-pro-BNP) in individuals with a GFR less than 60 mL/min/1.73 m^2 (<0.58 mL/s/m^2) (CKD G3a-G5), it is recommended that serum concentrations be interpreted with caution with respect to diagnosis of heart failure and assessment of volume status (a grade 1B recommendation).

Aspirin (ASA) is recommended for secondary prevention in all patients with CKD based on decreased mortality in observational studies.[100,101] ASA is generally not recommended for primary prevention as compared to placebo or no treatment as it reduces the risk of myocardial infarction but not all-cause mortality, CV mortality, or stroke and increases the risk of major and minor bleeding.[102,103]

Also of importance with regard to cardiovascular disease in patients with CKD is the fact that non-dialysis CKD patients now have more therapies available to delay CKD progression including sodium-glucose co-transporter type 2 (SGLT2) inhibitors (eg, canagloflozin, dapagloflozin), glucagon-like-peptide-1 (GLP-1) receptor agonists, and mineralocorticoid receptor antagonists (eg, finerenone) (see Chapter 62 for further discussion). While the primary reason these agents are prescribed relate to slowing CKD progression, the cardiovascular outcomes associated with use of these agents are important when considering the potential benefits of selecting a given agent.

Hyperlipidemia

CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. Although the concentrations of LDL are not uniformly increased in patients with kidney disease, these patients produce small, dense LDL particles that are more susceptible to oxidation and more atherogenic than larger LDL subfractions. Other lipid abnormalities include low HDL, increased VLDL, and increased triglycerides.[104,105] In patients with nephrotic syndrome, the major lipid abnormalities are elevation of plasma total and LDL cholesterol, with or without low HDL cholesterol, and elevated triglycerides. See Chapter e66 for a detailed discussion of the management of proteinuria in patients with glomerular disease.

The KDIGO Lipid Guideline recommends that a complete fasting lipid profile be performed in all adults with newly identified CKD (a grade 1C recommendation).[106] Follow-up lipid levels are not recommended unless the information may alter management (eg, assessing adherence to therapy or assessing CV risk in a patient <50 years and not currently on a statin). Reduction in the risk of CV events in patients with CKD has only been demonstrated with statins or a statin plus ezetimibe combination.[107]

Statins in Chronic Kidney Disease

8 Statins have been shown to decrease mortality and CV events in non-dialysis CKD patients, however, data are not as compelling in the ESKD population. Two trials (4D and AURORA) conducted in ESKD patients on hemodialysis did not show a benefit of statin therapy for primary prevention of cardiovascular events including non-fatal myocardial infarction, non-fatal stroke and death from cardiac causes.[105,106] The Study of Heart and Renal Protection (SHARP) trial was conducted after these trials and was a primary prevention trial that evaluated the effects of combined simvastatin (20 mg) and ezetimibe (10 mg) compared with placebo on time to first major vascular event (nonfatal MI or cardiac death, any stroke, or revascularization) in patients with no history of MI or coronary revascularization and included patients with CKD (6,247) and ESKD (3,023).[107] In all patients receiving combined therapy during the 4.9-year follow up period, there was a significant 17% reduction in the relative risk (RR) of major vascular events and a 32% reduction in LDL in the patients who were assessed as compliant with therapy (two-thirds were compliant). While overall these results are positive, the reduction in major atherosclerotic events was not significant for the dialysis subgroup, although the study was not powered to evaluate ESKD patients as a separate group. A subgroup analysis comparing dialysis versus non-dialysis patients showed no differences in the RR of CV events even after adjustment for the reduction in LDL. A subsequent meta-analysis of statins in dialysis patients indicated that they had no significant beneficial effect on major CV events, all-cause mortality, CV death, or myocardial infarction, and a trend toward increased strokes despite clinically relevant reductions in LDL cholesterol.[108] In contrast, a meta-analysis of statins in non-dialysis CKD showed significant reductions in major CV events, CV death, all-cause mortality; myocardial infarction but uncertain effects on stroke.[109] Now there are also more data to support statins in non-dialysis CKD patients than in ESKD patients for secondary prevention of atherosclerotic cardiovascular events.[105,110]

The KDIGO Lipid guidelines[106] make the following recommendations:

1. In adults aged 18 to 49 years with CKD but not treated with chronic dialysis or kidney transplantation, we suggest statin treatment in people with one or more of the following (Level 2A): known coronary disease (myocardial infarction or coronary revascularization); diabetes mellitus; prior ischemic stroke; estimated 10-year incidence of coronary death or non-fatal myocardial infarction greater than 10%.
2. In adults older than 50 years with eGFR less than 60 mL/min/1.73 m^2 but not treated with chronic dialysis or kidney transplantation, we recommend treatment with a statin or statin/ezetimibe combination (Level 1A).
3. In adults with dialysis-dependent CKD, we suggest that statins or statin/ezetimibe combination not be initiated. (Level 2A) However, in patients already receiving statins or statin/ezetimibe combination at the time of dialysis initiation, we suggest that these agents be continued (Level 2C).

The 2018 American Heart Association and the American College of Cardiology (AHA/ACC) guidelines on cholesterol recognize CKD as a risk factor for CV events and recommend that treatment with a moderate-intensity statin (or moderate-intensity statin therapy plus ezetimibe) can be considered in patients with non-dialysis CKD between the ages of 40 and 75 years and 10-year CV risk of 7.5% or higher.[111]

In addition to some of the controversies with statin therapy in CKD, the newer cholesterol lowering agents for the management of hyperlipidemia to reduce atherosclerotic CVD such as the PCSK9 inhibitors have not been evaluated across the spectrum of CKD except in secondary analyses and further data are needed to evaluate potential benefits beyond lipid lowering in CKD patients.[105,110]

Pruritus

Chronic pruritus (or uremic pruritus/itching) is among the many complications that patients with advanced CKD endure and has long been a problem without a directly linked etiology, which has made determination of treatment options a challenge. The diagnosis is made in patients with CKD when all other potential comorbid conditions associated with pruritus have been ruled out. CKD associated pruritus is estimated to occur in approximately 40% of ESKD patients, but this is thought to be an underestimate.[112] There is much variability in time of onset relative to dialysis, frequency of symptoms, and body distribution with up to 50% of patients experiencing generalized pruritis that is often symmetrical. Some patients experience more localized pruritus with the face, back and access arm, but common sites include the legs, back, and scalp. Over time other complications may occur such as impetigo, ulcerations, and increased risk of infections.[113,114] Regardless of location pruritus has a negative effect on patient quality of life with sleep disturbances and depression associated with this condition.[112–114]

The mechanisms of pruritus are not fully understood, which is part of the reason multiple interventions have been attempted. The release of compounds by keratinocytes, immune cells or neurons in the skin that promote inching (pruritogens) including histamine, prostaglandins, cytokines, neuropeptides and protases has been proposed.[114] Imbalances in the endogenous opioid system, particularly peripherally distributed kappa opioid receptors, have been explored as playing a key role.[113] Pruritus has also been associated with inadequate dialysis, elevated PTH, calcium and phosphorus; however these associations are inconsistent and their correction does not necessarily correlate with resolution of pruritus.[113] Pharmacologic interventions that have been implemented to address CKD associated pruritus include gabapentinoids, capsaicin, sertraline, mirtazapine, antihistamines, among other strategies, with variable success.[113]

⑨Until recently, there was no approved therapy for uremic pruritus in the United States. Difelikefalin, a peripheral kappa opioid receptor agonist, exerts antipruritic effects by means of activation of kappa opioid receptors on peripheral neurons and immune cells. Reductions in itch intensity and improvements in sleep and quality of life were demonstrated in phase 3 clinical trials which lead to the larger scale trial to evaluate efficacy and safety of difelikefalin in adult 378 HD patients with moderate to severe pruritus. Patients received either difelikefalin 0.5 μg/kg or placebo three times per week and improvements in itching intensity scores compared to baseline over a 12-week period were evaluated. Significantly more patients receiving difelikeflain (52%) had what was deemed a clinically significant (3 point) decrease in itching intensity score compared to 31% in the placebo group (primary outcome). There was also improvement in quality of life.[115] Adverse effects included diarrhea, dizziness, and vomiting. Based on these data difelikefalin was approved in 2021 for treatment of moderate to severe CKD associated pruritus in HD patients. This agent is approved at a dose of 0.5 μg/kg administer intravenously into the venous line of the dialysis circuit at the end of each HD treatment since this agent is extensively removed by HD.[116] Post approval data and patient reported outcomes with use of this agent will be of interest as difelikefalin begins to be used in clinical practice in the ESKD population.

CONCLUSION

Although efforts to delay progression of CKD are paramount, measures to diagnose and manage the associated secondary complications and comorbid conditions early in the course of the disease are also essential. There are many secondary complications of advanced CKD that worsen as kidney disease progresses. This chapter focused on common complications of advanced CKD for which pharmacologic therapies are available including anemia, CKD-MBD, and uremic pruritus. CV complications are also prevalent in the population with CKD and although data are sparse compared to the general population, mitigation strategies should be considered as CVD is the leading cause of mortality in patients with ESKD.

Involving a multidisciplinary team to address not only CKD but to effectively design and implement individual patient care plans often required in the CKD population that include extensive nonpharmacologic and pharmacologic interventions is logical. Pharmacists are well positioned to actively participate in the chronic disease and medication management of CKD and ESKD patients and should be part of the current and developing kidney care models within the nephrology environment.

ABBREVIATIONS

CERA	continuous erythropoietin receptor activator
CHOIR	Correction of Hb and Outcomes in Renal Insufficiency
CKD	chronic kidney disease
CREATE	Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta
CV	cardiovascular
CVD	cardiovascular disease
eGFR	estimated glomerular filtration rate
ESA	erythropoiesis stimulating agent
ESKD	end-stage kidney disease
FGF-23	fibroblast growth factor-23
GFR	glomerular filtration rate
GI	gastrointestinal
Hb	hemoglobin
Hct	hematocrit
HbA1c	glycated hemoglobin or hemoglobin A_{1c}
HD	hemodialysis
HIF	hypoxia inducible factor
HIF-PHI	HIF-prolyl hydroxylase inhibitors
